RAZOR *TO* SCHURZ

RAZOR, an implement used most commonly for shaving and frequently for cutting and shaping women's hair. Razors used for other purposes, such as scraping or slicing, are common tools in the home and in industry.

Prehistoric cave drawings indicate that early shaving implements included clam shells, shark's teeth, and sharpened flints. Flints are still used by primitive tribes in certain parts of the world. Some of the razors found in Egyptian tombs of the 4th millennium B.C. are of solid gold or copper. Nobles of later Egyptian history, who wore wigs, shaved their heads as well as their faces with razors, and priests had their entire bodies shaved every third day.

Excavations of Iron Age settlements in western Europe and Britain have established that warriors were buried with their razors as well as their swords. The 1st-century-B.C. Greek historian Diodorus Siculus described the Gauls as having shaven cheeks and long moustaches. According to Livy, the razor was introduced in Rome by Lucius Tarquinius Priscus (Tarquin), 5th legendary king of Rome, in the 6th century B.C. Romans considered shaving an effeminate Greek custom, however, and it was not generally adopted by them until the middle of the 5th century B.C., when a group of Greek-Sicilian barbers came to the mainland. Barber shops then appeared in Rome but were patronized only by those who could not afford slaves; the more prosperous citizens were shaved by their valets. The general Scipio Africanus was said to have been the first Roman to indulge in a daily shave.

In Britain, Sheffield became an international centre of the cutlery industry in the 18th and 19th centuries, and steel razors, with a great variety of ornamental handles, were made by highly skilled craftsmen who hollow-ground the blades individually. It was in Sheffield that Benjamin Huntsman produced the first crucible steel in 1740. Local manufacturers at first rejected this hard steel, but after its adoption in France were forced to recognize its superiority. (*See* SHEFFIELD: *Industries.*)

Safety Razor.—A razor with a guard along one edge—the forerunner of the modern safety razor—was advertised in the Sheffield Directory for 1828. In 1880 a hoe-shaped safety razor was manufactured in the U.S. Oliver Wendell Holmes endorsed it, reporting enthusiastically that with it "one cannot cut himself." Two additional types of safety razor were soon on the market, but the sales of all were modest. Shortly after the beginning of the 20th century, King C. Gillette patented and began to manufacture in the U.S. a safety razor with double-edged replaceable blades, which became very popular. In the early 1960s manufacturers in several countries produced stainless steel blades for safety razors that had the advantage of longer usage than the older steel blades.

Electric Razor.—Patents on electric razors were issued in the U.S. as early as 1900. The first to be successfully manufactured was the one on which Jacob Schick, a retired Army colonel, applied for a patent in 1928 and which he placed on the market in 1931. Competitive models soon appeared.

The principle of the electric razor is similar to that of the barber's hair clipper. The shearing head, driven by a miniature motor, is divided into two sections, the outer one consisting of a series of slots to grip the hairs as they rest against the skin, the inner one comprising a series of saw-edged blades. In some models the shearing head is round, in others flat, and there are variations in the number and design of the blades and in such devices as auxiliary clippers for trimming sideburns.

See BARBER; CUTLERY. (J. AY.)

RE (RA), Egyptian god of the sun, one of the most important gods in the Egyptian pantheon. He was thought to travel across the sky in his boat each day, and during the night in another boat to make his passage through the underworld, where, in order to be born again for the new day, he had to vanquish the evil deity Apophis. Originally Re was but one of many solar deities, and indeed at first was not prominent at all. Eventually, however, his worship came to pervade that of all other solar gods and also that of many of the animal-headed deities. Thus are found such syncretisms as Re-Horakhte, Amon-Re, Sebek-Re, and Min-Re, among others. In turn, aspects of other gods influence Re himself; and his falcon-headed appearance may originate from the association with Horus (*q.v.*). The influence of Re was spread by his active and powerful priesthood at On (Heliopolis; *q.v.*), which was the centre of his worship. The priesthood in turn owed its influence, or perhaps only its increase, to the fact that Re came to be the official god of the pharaohs. Beginning with the second dynasty, Re became part of the royal name (so first Nebre), and others follow at various intervals until the fourth dynasty when the name of every king after Khufu contains Re. Finally, in the fifth dynasty, every king is both the son

of Re and Re himself incarnate. This is the time of the great pyramids built by Khufu, Khafre, and Menkaure, and of the great obelisk temples to Re at Heliopolis itself.

With the resurgence of Egyptian power during the 18th dynasty, Re is associated with Amon (*q.v.*) of Thebes as Amon-Re, a god closely connected with the rulers. Indeed the revolutionary worship of Aton during the abortive Amarna period in the 18th dynasty (*see* IKHNATON) may well have been influenced by the theology of Heliopolis; and, of course, Aton is the disk of the sun whose worship had previously existed under the general heading of Re worship.

Like all other important solar gods, Re was worshiped or treated primarily as a creator god. Such creation myths as are known are influenced by Egyptian syncretism and universalism, so that stories about Re are similar to those of other gods (*see* CREATION, MYTHS OF). Nonetheless the earliest of these, carved on the pyramid of Neferkare (sixth dynasty), represents Re as rising from the ocean of chaos on the primeval hill, creating himself and then in turn the other eight gods who form one of the enneads (groups of nine) of Egyptian gods, Shu, Tefnut, Geb, Nut, Isis, Osiris, Set (Setekh), Nephthys. *See* also EGYPT: *History: Ancient Religion.* (J. F. O.)

RÉ, ÎLE DE, an island in the Bay of Biscay, 1½ mi. (2.4 km.) off the west coast of France opposite La Pallice and La Rochelle, and included in the *département* of Charente-Maritime. Pop. (1962) 9,484. It covers an area of 33 sq.mi. (85 sq.km.), and is aligned northwest-southeast for 18 mi. (29 km.), with a breadth of usually 2 to 3 mi. (3 to 5 km.), but on the east coast an indentation, the Fier d'Ars, nearly divides it, leaving an isthmus only 80 yd. (73 m.) across. The island is separated from the coast of Vendée to the north by the shallow water of the Pertuis Breton. It is low-lying, surrounded by limestone reefs that enclose a marshy area in the north, and is scenically uninteresting. There is a considerable amount of cultivation of early vegetables (especially asparagus) and there are extensive salt fields and oyster beds along the coast. The chief settlements are Saint-Martin-de-Ré, a port on the north coast (with fortifications by Vauban), and La Flotte, a little fishing port and bathing resort. There are ruins of the medieval abbey of Saint-Laurent. (AR. E. S.)

REACTION KINETICS is that branch of physical science which deals with the determination and interpretation of the rates of chemical change. The subject includes the consideration of the rates both of everyday but complicated reactions such as hard-boiling an egg (an example of protein coagulation) and of simpler but less commonplace reactions such as the one between hydrogen and chlorine. Rates have been measured for slow reactions (*e.g.*, the disintegration of ordinary uranium, only half of which will decompose in 5,000,000,000 years) and for fast reactions (*e.g.*, the combination of hydrogen and sulfate ions, which may be half complete in about a billionth of a second). An attempt is made in each case to show quantitatively the effect of changes in the experimental conditions upon the reaction velocity, and to describe in as much detail as possible the behaviour of the molecules at the moment of their reaction.

Many familiar processes involve chemical reactions which proceed at measurable rates. For example, the rusting of iron, the fermentation of sugar, the "drying" of paint, the hardening of plaster of Paris, the baking of bread and the growth of plants, all involve chemical reactions of greater or lesser complexity, and for each example there is considerable interest in the rate of reaction. In general, these familiar processes are very complex, partly because many of the materials are not single pure compounds, but mixtures. It is well known, however, that the rusting (oxidation) of iron requires both air and water, and that the reaction proceeds much more rapidly near the ocean (where salt is deposited on the iron) than it does elsewhere. The rate of rusting also depends upon the composition of the metal (pure iron and stainless steel corrode less rapidly than do cast iron and mild steel) and on temperature (corrosion is rapid in a stream of steam and air). (*See* CORROSION AND OXIDATION OF METALS.)

Scientists have been largely concerned with measuring the rates of reactions such as the decomposition of ozone, the oxidation of sulfur dioxide and the nitration of hydrocarbons; they assume that an understanding of these and similar reactions of pure chemicals will eventually lead to an understanding of more complex (if more familiar) reactions.

Studies of reaction velocity have not only played a fundamental role in the growth of theoretical chemistry; the concepts developed in these studies have also been highly fruitful in industry, especially in the field of catalysis (*q.v.*). A case in point is the Haber process for the manufacture of ammonia (*q.v.*), which is based in part on studies of reaction kinetics. Both theoretical and practical research in the field of reaction kinetics was by mid-century under way in hundreds of laboratories.

A specific example of a rate study is the work on the decomposition of hydrogen iodide to form hydrogen and iodine.

$$2HI \longrightarrow H_2 + I_2 \qquad (1)$$

This reaction proceeds at a rate convenient for measurement in the neighbourhood of 320° C., at which temperature not only the hydrogen and hydrogen iodide but even the iodine is gaseous. (This reaction is a reversible one; however, for the moment, it is better to postpone discussion of this complication and to consider only the reaction as written.) The rate of decomposition of hydrogen iodide increases as the quantity of hydrogen iodide per unit volume is increased; quantitatively, the rate is proportional to the square of the concentration of hydrogen iodide. The rate increases by a factor of 1.9 when the temperature is increased from 320° C. to 330° C. The reaction occurs within the body of the gas, and not on the glass walls of the vessel in which the experiment is performed.

The facts just cited have been interpreted to indicate that when two molecules of hydrogen iodide collide, a chemical change occurs only if the velocity of one of them with respect to the other exceeds 2.4 km./sec. (about 5,000 m.p.h.). The average diameter (so far as collision is concerned) of these hydrogen iodide molecules can also be calculated from the kinetic data; it is of an order of magnitude (0.8×10^{-8} cm.), roughly consistent with the results of other measurements of the sizes of molecules. The effective collisions (*i.e.*, those which lead to reaction) result in a simple interchange of atoms; here the hydrogen and iodine atoms in each of the two colliding molecules of hydrogen iodide separate; simultaneously, the two hydrogen atoms combine to form a hydrogen molecule, and the two iodine atoms combine to form an iodine molecule.

For the discussion of even the simple example of the decomposition of hydrogen iodide, it has been necessary to employ the elementary concepts of chemistry (*q.v.*) and of the kinetic theory of matter (*q.v.*). For the more detailed treatment of reaction kinetics which follows, a somewhat more extensive knowledge of these subjects is assumed. In the last sections of this article, a more sophisticated presentation is attempted.

History.—Gross differences in the rates of chemical reactions have long been recognized. By the beginning of the 19th century, several instances were known where the rate of a chemical change could be greatly increased by adding to the reacting system a small quantity of some apparently inert material. For example, it was discovered in 1796 that the dehydrogenation of alcohols proceeds much more rapidly in the presence of metals than it does in their absence. In 1836, Jöns Jacob Berzelius grouped together many reactions of this type and gave the name "catalysts" to the materials which accelerate chemical change. (The modern definition of catalysts is given below.) Although the qualitative concept of reaction rate was by that time well established, the first quantitative measurement and mathematical formulation of reaction velocity is generally credited to L. F. Wilhelmy, who, in 1850, measured the rate of "inversion" (hydrolysis) of cane sugar.

Definitions.—Chemical reactions can be classified as homogeneous or heterogeneous. Homogeneous reactions are those (like the decomposition of hydrogen iodide) which occur completely within one phase (gaseous, liquid or solid). Heterogeneous reactions are those (like the reaction between a metal and an acid) in which the reactants are components of two or more phases (solid and gas, solid and liquid, two mutually immiscible liquids, etc.) or in which one or more reactants undergo chemical change at an interface; *i.e.*, on the surface of a solid catalyst.

Reactions may also be classified as "reversible" or "irreversible." An irreversible reaction is one in which the reactants, if mixed in the proper proportions, are almost completely converted to the reaction products; a reversible reaction is one in which appreciable quantities of all the reactants and of all the reaction products are present in the system no matter how long the reaction is allowed to proceed. The mixture eventually formed in such a reversible reaction is called the equilibrium mixture; the same equilibrium mixture may be prepared from suitable amounts of either the reactants or the reaction products. For example, the same equilibrium mixture of hydrogen, iodine and hydrogen iodide (at definite temperature and pressure) can be prepared by starting either with equivalent quantities of hydrogen and iodine or with pure hydrogen iodide. If the definition of equilibrium is that adopted in thermodynamics (*q.v.*), then every reaction is, in principle, reversible. There are reactions, however, where the extent of the reverse reaction is too small to be detected by any experimental means at present known; such reactions are usually regarded, for the purposes of kinetics, as irreversible.

"Order" of Reaction.—The fundamental law of reaction kinetics was developed by the Norwegian chemists C. M. Guldberg and P. Waage around 1867 (a similar formulation was made independently by Jacobus Hendricus van't Hoff). They assumed that, at constant temperature, the rate of any simple chemical reaction is proportional to the product of the concentrations of the various reacting substances. They showed in a general way that their law of chemical change is consistent with the kinetic molecular theory of matter, and that the data for many chemical reactions could be formulated quantitatively in terms of their theory. Since 1870, the concepts of Guldberg and Waage have been extended and modified, but most of reaction kinetics is still based upon their work.

Consider the simple homogeneous, irreversible reaction between two compounds, A and B (the reactants), to form C and D (the reaction products).

$$A + B \longrightarrow C + D \qquad (2)$$

An example of this sort of reaction is the saponification of ethyl acetate by alkali:

$$\underset{A}{CH_3CO_2C_2H_5} + \underset{B}{OH^-} \longrightarrow \underset{C}{CH_3CO_2^-} + \underset{D}{C_2H_5OH} \qquad (2')$$

Equations (2) and (2′) as written represent the stoichiometry of the chemical change; *i.e.*, the equations show the relationship between the weights of the initial reactants and those of the final products. The reaction rate may be proportional to the concentrations of the reactants which appear in the stoichiometric equation; if, however, the reaction occurs in several consecutive chemical steps, or requires a catalyst, the kinetics may be more complicated (*see* below) than those which could be implied from the stoichiometry.

The treatment for a simple case follows. At the beginning of the reaction, the compounds A and B are present in definite concentrations, say a_0 and b_0 moles per litre respectively[1]; the concentrations of C and D are zero. As the reaction proceeds, the concentrations of A and B decrease, whereas the concentrations of C and D increase. If the concentrations of A and B at any instant are represented by the symbols (A) and (B), then the law of Guldberg and Waage states that wherever equation (2) represents the true kinetic course of the reaction, the reaction velocity, v, is proportional to (A) and to (B). This statement in mathematical form is

$$v = k(A)(B) \qquad (3)$$

where k, the proportionality factor, is called the rate constant. Note that the rate of reaction, v, and the rate constant, k, are not the same, but are connected by an equation of the form of (3).

An equation such as (3) may accurately describe the rate of a chemical reaction. Unfortunately, however, a good experimental method for directly measuring the rate, v, of a reaction is usually not to be found. The quantities which can usually be determined experimentally are the time and the concentrations of the reactants or reaction products. An equation such as (3) can be transformed by the methods of calculus (*q.v.*) into an equation expressing a relationship between these concentrations and time. Although the details of this transformation are in no way necessary for the succeeding argument, they are nevertheless presented here for the sake of continuity.

If the concentration of C at any instant is represented by x, then the rate, v, of formation of C is dx/dt, the derivative of x with respect to time; and equation (3) can be replaced by (3′).

$$v = \frac{dx}{dt} = k(A)(B) = k(a_0 - x)(b_0 - x) \qquad (3')$$

The integrated form of equation (3) is

$$\log_e \frac{b_0(a_0 - x)}{a_0(b_0 - x)} = kt(a_0 - b_0) \qquad (4)[2]$$

where t is the time measured from the beginning of the reaction; the other symbols have been previously defined. In principle, it should be possible to obtain for every reaction an equation, analogous to (4), from which the concentrations of the various reactants and products at any moment may be calculated.

One method of testing experimentally whether equations (3) and (4) adequately describe the rate of any particular reaction is to measure x (the concentration of C) at several different times, t. An attempt is then made to choose a single value for the rate constant k such that all the sets of corresponding values of x and t satisfy equation (4). If this attempt is successful, the experiment is then repeated at the same temperature but with different initial concentrations (a_0 and b_0) of A and B. If and only if these new data also satisfy equation (4) with the rate constant k unchanged, the demonstration that the reaction obeys the rate equations (3) and (4) is complete. The constant, k, is thus independent of the initial concentrations of A and B; it is, however, a function of the temperature and it depends of course upon the chemical nature of the reactants A and B. Fig. 1 is a graphical representation of equation (4) for the saponification of ethyl acetate.

If the equations for various chemical reactions are treated as was equation (3) for reaction (2′), then these reactions fall into a number of different classes. A reaction the rate of which may be described by an equation of the form

$$v = k(A) \qquad (5)$$

is called a first order reaction; one described by an equation of the form

$$v = k(A)^2 \quad \text{or} \quad v = k(A)(B) \qquad (6) \text{ or } (6')$$

is called a second order reaction, etc. In general, a reaction the rate of which may be described by the equation

$$v = k(A)^m(B)^n(C)^p(D)^q \ldots\ldots \qquad (7)$$

is called a reaction of order r, where $r = m + n + p + q + \ldots\ldots$. Such a reaction is said to be of order m with respect to A, of order n with respect to B, etc. (Some reactions may be of nonintegral order; *e.g.*, half-order. The majority of known reactions are of first or second order.)

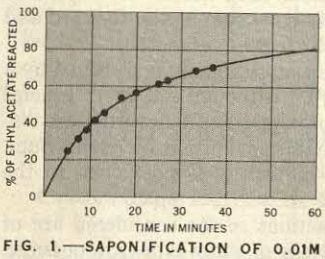

FIG. 1.—SAPONIFICATION OF 0.01M ETHYL ACETATE WITH 0.01M NaOH AT 25° C. DOTS ARE EXPERIMENTAL POINTS; LINE IS THEORETICAL FOR $k = 6.5$ $Min^{-1}M^{-1}$

In certain reactions, such as the inversion of cane sugar,

$$C_{12}H_{22}O_{11} + H_2O \rightarrow 2C_6H_{12}O_6 \qquad (8)$$

the rate is proportional to the concentration of some substance (in this instance, the hydronium ion of the acid) (*see* ACIDS AND BASES), which does not appear among either the reactants or the reaction products in the chemical equation; the reaction cited (equation [8]) is said to be catalyzed by hydronium ion H_3O^+, or hydrated hydrogen ion.

$$v = k(C_{12}H_{22}O_{11})(H_3O^+) \qquad (9)$$

If the catalyst is one of the reaction products, the reaction is said to be autocatalyzed.

Reversible Reactions.—The reactions hitherto described have been assumed to be irreversible, in the sense defined above. If the reaction between the compounds A and B, on the one hand,

[1] For reactions in the gas phase, the partial pressure of each gas is used as a measure of its concentration.

[2] Where $a_0 = b_0$, the corresponding equation is $\frac{x}{a_0(a_0 - x)} = kt \qquad (4')$

and C and D, on the other, is reversible, then equation (2) must be rewritten.

$$A + B \rightleftarrows C + D \qquad (2'')$$

Wherever equation (2″) represents the true kinetic course of the reactions, the rates v_f of the "forward" and v_r of the "reverse" reactions are given by equations (10) and (10′).

$$v_f = k_f(A)(B) \qquad (10)$$

$$v_r = k_r(C)(D) \qquad (10')$$

If the reaction is begun by mixing A and B (either pure or in solution), the initial concentrations of C and D are each zero; hence the rate, v_r, of the reverse reaction is also zero. However, as A and B react to form C and D, these products in turn react to regenerate A and B. The net rate at which C and D are formed is therefore the difference between v_f and v_r.

$$v = v_f - v_r = k_f(A)(B) - k_r(C)(D) \qquad (11)$$

The net rates of the forward and reverse reactions for a particular case are shown graphically in fig. 2. In the reaction in question, a mixture of the two tautomers (*see* TAUTOMERISM) of bromonitrocamphor is formed both from the normal (N) and from the pseudo (P) isomer.

The rate at which the equilibrium mixture is formed from pure N is shown in the upper curve; the rate at which the equilibrium mixture is formed from pure P is shown in the lower curve.

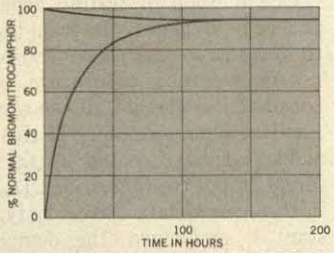

FIG. 2.—RATES AT WHICH EQUILIBRIUM IS ESTABLISHED BETWEEN THE TWO FORMS OF BROMONITROCAMPHOR

As the latter reaction proceeds, P is converted into N; hence, the forward rate decreases and the reverse rate increases. Eventually, the two rates become equal, and the net rate, v, is zero; thus, a dynamic equilibrium is achieved. This state of dynamic equilibrium is not a condition in which no reaction occurs, but is one in which the rates of the forward and reverse reactions are equal. This kinetic concept of dynamic equilibrium has been experimentally verified by the use of radioactive tracers (*see* ISOTOPE).

When, for a reaction which follows equation (2″), the forward and reverse reactions proceed at equal rates, it is seen that

$$v_f = v_r = k_f(A)(B) = k_r(C)(D) \qquad (12)$$

From equation (12) it follows that

$$\frac{(C)(D)}{(A)(B)} = \frac{k_f}{k_r} = K_e \qquad (13)$$

where K_e, the ratio of the rate constants for the forward and reverse reactions, is called the equilibrium constant. Equation (13) gives the relative concentrations of the compounds A, B, C, and D at equilibrium; these concentrations need not be even approximately equal, for in general the rate constants of the forward and reverse reactions differ considerably from one another.

An equation analogous to (13) but more general is obtained by a parallel treatment of a reaction (7). Although this more general expression is correct as a first approximation, it nevertheless disagrees with the precise thermodynamic definition of equilibrium. Consideration of this and similar difficulties is postponed to the sections on collision theory and on activated-complex theory.

Complex Reactions.—The reactions so far considered are of simple types; all sorts of combinations of these types are possible. For example, reactions sometimes occur in several steps.

$$A \rightarrow B \rightarrow C \qquad (14)$$

Here the rate of formation of B is proportional to the concentration of A, and the rate of formation of C is proportional to the concentration of B. Since, initially, the concentration of B is zero, the initial rate of formation of C is zero. Fig. 3 shows graphically the concentration of C at any time, t, in a system where the rate constants for the two consecutive reaction steps are of comparable magnitude. Other cases of interest are those in which one of the successive reactions is reversible, or of second order, etc. Considerable complexity is not only possible but common.

What has already been said makes it evident that the kinetic equation for a reaction cannot be inferred from the chemical equation, which gives only the relationship between the weights of reactants which will combine with one another and the weights of the final products (*i.e.*, the stoichiometric relations). The kinetic expression, it is true, must account for the stoichiometric findings, but it should do more than that. Usually more than one reaction path between the initial reactants and the final products is conceivable. Under favourable conditions kinetic considerations permit the selection of just one of these reaction paths, and kinetic measurements demonstrate that the path selected, and no other, is the one which the reaction takes. Under less favourable conditions, kinetic considerations are insufficient to eliminate all reaction paths but one. Even here, however, they serve to rule out many of those paths which from mere stoichiometric considerations might be considered possible.

A simple example will illustrate the ideas just expressed. A chemist might investigate an irreversible reaction, the stoichiometric expression for which is $A \rightarrow C$. This expression means that each molecule of the reactant A is converted (eventually) into one molecule of the product C. It does not tell whether each molecule of A is converted directly into a molecule of C or whether each molecule of A is converted first into a molecule of an intermediate, B, which is in turn converted into a molecule of C. In the former instance, the proper kinetic expression for the reaction $A \rightarrow C$ may coincide with the stoichiometric expression. In the latter instance, the proper kinetic expression is $A \rightarrow B \rightarrow C$. Measurements of the extent of the reaction at various stages in its course are often sufficient to decide questions of the kind here raised. In the particular instance cited, if the reaction followed a curve of the sort shown in fig. 3, that fact would show that the kinetic expression for the reaction was $A \rightarrow B \rightarrow C$. If, on the other hand, the reaction followed a curve predicted from equation (5), and somewhat resembling the one shown in fig. 1, that fact would show that the kinetic expression for the reaction was $A \rightarrow C$, coinciding with the stoichiometric expression. This fact alone would not rule out compound B as an intermediate, but it could be an intermediate in the reaction only under certain special circumstances (*i.e.*, the reaction $B \rightarrow C$ would have to be very fast as compared with the reaction $A \rightarrow B$).

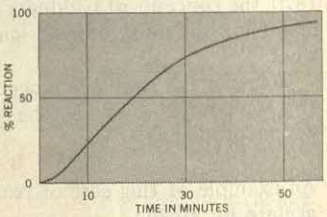

FIG. 3.—SUCCESSIVE FIRST ORDER REACTIONS, WHERE THE RATE CONSTANT OF THE SECOND IS FOUR TIMES AS GREAT AS THAT OF THE FIRST (DIAZOTIZATION OF PHENYL MERCURIC NITRATE IN 20% HNO_3 WITH 0.16M HNO_2)

If any individual reaction is to be thoroughly understood, its reaction kinetics must be investigated. The object in view is to determine by inference from the kinetic measurements whether the reaction proceeds in one or more stages, to determine the order of each reaction stage with respect to each one of the reactants, and to determine for each particular stage whether or not it is catalyzed by some substance (possibly an ion) which does not appear in the stoichiometric expression for the over-all reaction. It should, however, be stated that kinetic considerations by themselves, although they greatly aid in the treatment of the problem stated, are often insufficient for its solution in all details.

If a kinetic study shows that two molecules (of the same or of different compounds) react with one another directly, then the reaction is said to be bimolecular. In a many-stage reaction, some individual step may be bimolecular, although the over-all reaction is not of second order and may indeed (like [14]) be of no definite order. It is likewise possible for a reaction to be of the second order, but to contain no single step which is truly bimolecular. The interpretation of the reaction kinetics for any individual reaction is thus a difficult matter, and for many important reactions the conclusions are still tentative.

Application of the Kinetic Molecular Theory.—Guldberg and Waage assumed that the rate of any reaction is proportional to the product of the concentrations of the reactants (equation [7]); they interpreted this hypothesis in terms of the kinetic molecular

theory. The number of collisions between the molecules of compound A and the molecules of compound B is proportional to the product (A)(B) of their concentrations; Guldberg and Waage's law amounts then to a statement that molecules react only if they collide, and that the rate at which they react is proportional to the number of collisions per second.

But although reaction between two molecules cannot occur unless these molecules collide, it does not follow that reaction must occur every time two molecules collide, even though these are molecules of substances which can react chemically one with another. For most reactions, it has been fully determined that the vast majority of collisions are "elastic"; *i.e.*, that the molecules rebound from one another without chemical reaction. It is possible by means of the kinetic molecular theory to compute the number of collisions per second between the molecules of two compounds which are present in a solution or a gas in known concentrations. For example, the number of collisions between pairs of molecules of hydrogen iodide at a temperature of 320° C. and a total pressure of one atmosphere is approximately 10^{28} per cubic centimetre per second. Under the conditions stated, there are only about 10^{19} molecules of hydrogen iodide in a cubic centimetre of gas. Hence, if every collision between two molecules of hydrogen iodide led to chemical change, the reaction would be over in a small fraction of a second, almost too short a time to measure. It has been computed that in the system described, only one collision in about 10^{15} leads to chemical change.

Temperature Coefficients of Reaction Rates.—Another (and historically older) consideration leading to the conclusion that not all collisions cause reaction is based on the increase of reaction rates with increase in temperature. According to kinetic-molecular theory, the number of collisions between molecules of two compounds present at definite concentrations increases as the square root of the absolute temperature. For example, the number of collisions at 25° C. (298° absolute) is only about 1.5% greater than the number at 15° C. (288° absolute). But the rates of most reactions increase by a factor of two or more when the temperature is raised by 10° C.; as much material may react in an hour at 100° C. as in a year at 0° C. In some instances, such as the denaturation of egg albumin, the reaction rate increases one hundredfold when the temperature is raised 10° C.

However, the assumption that only those molecules which collide with high energy of impact react with one another not only furnishes an explanation for the high temperature coefficients of reaction rates, but also accounts for the fact that collisions effective in bringing about chemical change are usually rare. To bring out the connection between the assumption and the conclusions, it is necessary to consider the velocity of one molecule relative to another. This relative velocity is not the same for all colliding pairs, but there is a determinable probability that for any one particular pair the relative velocity will lie close to any chosen value, u, of the relative velocity. This probability is calculated from the Maxwell-Boltzmann distribution curve (*see* KINETIC THEORY OF MATTER) shown in fig. 4 and 5 for hydrogen iodide at 300° C. and 400° C. The horizontal co-ordinate represents the velocity, μ, in km./sec., of one molecule of hydrogen iodide relative to the one with which it collides; the vertical co-ordinate represents the probability that the relative velocity is μ. (More precisely, the ordinate is equal to $1/N_0{}^2 d(N^2)/d\mu$, where N_0 is the total number of molecules under consideration, and $d(N^2)$ is the number of pairs of molecules with velocity lying between μ and $\mu + d\mu$.) Fig. 5 is an enlargement in vertical scale of part of fig. 4. Fig. 4 and 5 indicate (1) that only a minute number of molecular pairs have relative velocities in excess of the 2.4 km./sec. required for reaction (*see* above), and (2) that, although the average value of the relative velocity is not greatly increased by raising the temperature from 300° C. (573° absolute) to 400° C. (673° absolute), the number of molecular pairs with high relative velocities is increased by a large factor. Thus the assumption that reaction is limited to molecular pairs with high relative velocities at the moment of collision qualitatively explains both the fact that few collisions are "effective" in producing reaction and the fact that the rates of most chemical reactions increase sharply with increase in temperature.

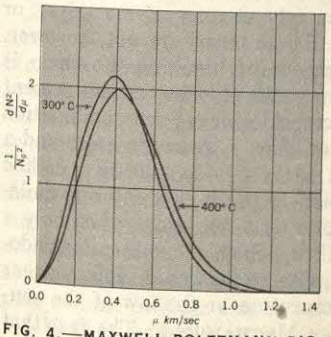

FIG. 4.—MAXWELL-BOLTZMANN DISTRIBUTION OF PAIRS OF MOLECULES OF HYDROGEN IODIDE (AT 300° C AND AT 400 C°). THE VELOCITY OF ONE MEMBER OF ANY PAIR RELATIVE TO THE OTHER MEMBER IS μ

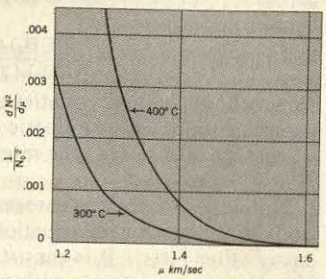

FIG. 5.—EXPANDED SCALE DRAWING OF HIGH-VELOCITY END OF FIG. 4

The complete equation (24) for the reaction rate derived from the kinetic collision theory is given in the next to last section of this article. Here it is sufficient to say that this complete equation is consistent (within experimental error) with an empirical equation (15) advanced by Svante August Arrhenius in 1889 which has proved useful.

$$\log_e \frac{k_2}{k_1} = \frac{Q}{R}\left(\frac{I}{T_1} - \frac{I}{T_2}\right) \qquad (15)$$

In equation (15) k_1 and k_2 are the rate constants at the absolute temperatures T_1 and T_2 respectively, Q is a constant called the activation energy, and R is the gas constant (1.98 cal./mole degree) ($\log_e$ refers to natural logarithms). The larger the value of Q, the more sensitive is the reaction rate to changes in temperature. Reactions with values of Q varying from less than 500 up to about 100,000 cal./mole have been discovered. Q divided by the number of molecules in a mole (Avogadro's number) is (roughly) equal to the relative kinetic energy of a molecular pair which is just sufficient to make the members of the pair react upon collision.

Reaction Mechanism.—In this section, it will be shown how reaction kinetics may be used to determine the path or mechanism of a somewhat puzzling reaction. The example chosen is the reaction in aqueous solution between acetone and bromine. Here the stoichiometric

$$CH_3COCH_3 + Br_2 \longrightarrow CH_3COCH_2Br + HBr \qquad (16)$$

expression (16) is of the same form as equation (2). In 1904, however, A. Lapworth discovered that the rate of this reaction is proportional to the concentration of the acetone and of the hydrogen bromide (one of the reaction products) but independent of the concentration of the bromine and of all other substances known to be present in the system. The kinetic equation, therefore, is

$$v = k(CH_3COCH_3)(HBr) \qquad (17)$$

These facts suggest the hypothesis that the acetone is slowly converted into some reactive intermediate by the action of the acid; this reactive intermediate then combines rapidly with bromine. The hypothesis has more recently been elaborated as follows:

$$(CH_3)_2CO + H_3O^+ \rightleftharpoons (CH_3)_2COH^+ + H_2O \text{ ("steady state" rapidly reached)} \qquad (18)$$

$$(CH_3)_2COH^+ + H_2O \longrightarrow CH_3\underset{\displaystyle OH}{\overset{\displaystyle |}{C}} = CH_2 + H_3O^+ \text{ (slow reaction)} \qquad (18')$$

$$CH_3\underset{\displaystyle OH}{\overset{\displaystyle |}{C}} = CH_2 + Br_2 \longrightarrow CH_3COCH_2Br + HBr \text{ (rapid reaction)} \qquad (18'')$$

The proposed reaction between the catalyst and the acetone results in the transformation of the acetone into a reactive intermediate (the "enolic" modification of acetone; *see* TAUTOMERISM), which subsequently reacts rapidly with bromine. The rate, v, of the entire reaction is equal to that for the slowest step in the process, namely reaction (18′). The kinetic equation for this step is

$$v = k'((CH_3)_2COH^+) \qquad (19)$$

The concentration of water is essentially constant and does not enter into equation (19); its concentration can be included in the rate constant, k'. The ion $(CH_3)_2COH^+$ would be in equilibrium with the acetone and acid present in the solution if it were not for the reactions (18′) and (18″) which slowly but essentially ir-

reversibly remove some of this ion.

The ion $(CH_3)_2COH^+$ is described as in pseudoequilibrium with acetone and acid, or as in a "steady state." The "steady state" concentration of the ion is given to a good approximation by the equilibrium expression

$$\frac{[(CH_3)_2COH^+]}{[(CH_3)_2CO][H_3O^+]} = K \qquad (19')$$

When the theoretical equations (19) and (19′) are combined, the experimentally verified kinetic equation (17) for the bromination of acetone is obtained; the rate constant k is the product of k' and K.

Not only does the mechanism presented in equations (18), (18′) and (18″) agree with equation (17), but it will further explain many other facts. It is consistent, for example, with the observation that acetone reacts with chlorine, or with iodine at the same rate as it does with bromine. This is in accord with the proposed mechanism, since equation (18′), which does not involve the halogen at all, is postulated as the rate-determining step in the halogenation.

A more detailed investigation of the reaction has revealed that it is catalyzed not only by hydronium ion but also by molecules of un-ionized acids; it is also catalyzed by bases. The catalysis by un-ionized acid molecules can be accounted for by substituting equation (18‴) for equation (18′)

$$(CH_3)_2COH^+ + B \longrightarrow CH_3\underset{\displaystyle OH}{\overset{\displaystyle |}{C}}=CH_2 + BH^+ \qquad (18''')$$

where B represents a molecule of any base. (The detailed mathematical analysis needed to prove the above statement, although beyond the scope of this article, is treated by L. P. Hammett in *Physical Organic Chemistry.*) Furthermore, the kinetic isotope effects (*see* below, *Reactions of Isotopes*) with deuterium and tritium strongly support the reaction scheme; in analogous but more complicated examples, the stereochemical predictions of the mechanism have been verified.

The proposed mechanism is thus consistent with a large and varied selection of quantitative kinetic evidence. This is a necessary condition, but not a sufficient one to establish the mechanism; it does, however, make the proposed mechanism quite probable.

Catalysis.—A catalyst is defined as a substance which increases the rate of a chemical reaction, but which can be recovered quantitatively and unchanged at the end of the reaction. There are many substances which (for specified reactions) approach this definition closely. Typical examples of homogeneous catalysis are the action of acids to increase the rate of hydrolysis ("inversion") of cane sugar, the action of bases to increase the rate of polymerization in the preparation of bakelite, the action of oxides of nitrogen in the chamber process for manufacturing sulfuric acid. Typical examples of heterogeneous catalysis are the action of finely divided iron to increase the rate at which nitrogen and hydrogen combine to form ammonia, the action of vanadium pentoxide to increase the rate at which sulfur dioxide and oxygen combine to form sulfur trioxide in the contact process for manufacturing sulfuric acid, and the action of finely divided nickel to increase the rate at which hydrogen combines with vegetable oils to form solid fats (*e.g.*, "Crisco"). (For a discussion of theory, manufacture and use of catalysts *see* CATALYSIS.)

Catalysts accelerate chemical reactions in various different ways. The bromination of acetone (cited above) illustrates one of the most common modes of action. Here the acid which in this case is the catalyst combines with one of the reactants (acetone) to form an intermediate chemical compound. Then, in a later step of the complex reaction, the catalyst is regenerated and so becomes available for further reaction. In this way the catalyst goes through a complete cycle, and a trace of catalyst increases the rate at which a large amount of material reacts.

It is interesting to note that a catalyst can increase the rate of a chemical reaction but cannot change its point of equilibrium. If this statement were not correct, it would be possible to construct a perpetual motion machine. Since perpetual motion is an impossibility (*see* THERMODYNAMICS), it follows that in a reversible reaction the catalyst must accelerate both the forward and the reverse rate and in the same proportion.

Photochemical Reactions.—Reactions which take place in the presence of light but not in the dark are called photochemical reactions; their rate depends upon the amount of light absorbed. This subject is treated fully in the article on PHOTOCHEMISTRY. The principles here needed are the following: (1) Only the light which is absorbed by the system is effective in promoting chemical change; (2) radiant energy (light) is available only in units called quanta (*see* LIGHT); (3) a molecule which absorbs light and is thereby activated (*i.e.*, enters into a reaction with light) absorbs one and only one light quantum (A. Einstein). Subsequently, the activated molecule may enter into other, more complicated chemical reactions.

Chain Reactions.—Hydrogen gas reacts with chlorine at room temperature provided that the mixture is illuminated; the reaction (except under special circumstances, *see* below) does not occur in the dark. The form of the equation for the chemical reaction

$$H_2 + Cl_2 \longrightarrow 2HCl \qquad (20)$$

resembles that of the reaction for the formation of hydrogen iodide (reverse of equation 1); the kinetics of the two reactions are, however, quite different. The reaction between hydrogen and chlorine proceeds when visible light is used. Since light of this wave length is absorbed by chlorine, but not by hydrogen, it follows that chlorine is the reactant affected by the light. Measurements have shown that as many as 1,000,000 molecules of hydrogen chloride are produced for every light quantum absorbed. Evidently a very special mechanism must be postulated to account for this fact.

It has been assumed (W. Nernst, M. Bodenstein) that, as an indirect or direct result of the illumination, the molecules of Cl_2 which absorb light quanta are dissociated into chlorine atoms (21). These atoms then react as shown in equations (21′) and (21″).

$$Cl_2 \longrightarrow 2Cl \qquad (21)$$

$$Cl + H_2 \longrightarrow HCl + H \qquad (21')$$

$$H + Cl_2 \longrightarrow HCl + Cl \qquad (21'')$$

Each chlorine atom obtained by the illumination reacts with a molecule of hydrogen to produce a molecule of hydrogen chloride and an atom of hydrogen (21′); the latter in turn reacts with a molecule of chlorine to produce another molecule of hydrogen chloride and to regenerate an atom of chlorine (21″). The cycle is then repeated. Reactions characterized by such cycles are called chain reactions. If there were no side reactions to destroy the intermediate hydrogen and chlorine atoms, then, in principle, one chlorine atom could convert all the hydrogen and chlorine in the system to hydrogen chloride. In fact, the chain length varies from a few units to a million, depending upon the experimental conditions. The chains are broken (or terminated) when the chlorine or hydrogen atoms are removed. There are several means of removing these reactive atoms. For example, oxygen combines with either chlorine or hydrogen atoms, and traces of oxygen are effective in decreasing the rate of the reaction in question. In this reaction then, oxygen acts as a negative catalyst, or an inhibitor, or a chain breaker. (These terms are not, however, exactly synonymous.) Another means of breaking the chain is the combination of hydrogen atoms and chlorine atoms present in the gas mixture to form hydrogen chloride. Such combination occurs on the walls of the vessel, or when a hydrogen atom and a chlorine atom, in what is called a three-body collision, collide simultaneously with some third particle (such as a chlorine molecule); interestingly, the combination does not occur when only a hydrogen and a chlorine atom collide. Such a combination independent of the wall or of any third particle would violate either the law of the conservation of momentum or the law of the conservation of energy, or both. (*See* MECHANICS.) The fact that no such combination is observed simply means that the molecular system in question obeys the laws of mechanics, as do the molecular systems in all similar reactions which have been carefully studied.

The validity of the proposed chain mechanism for the reaction between hydrogen and chlorine is supported (1) by the high photo-

chemical yield of the reaction (*i.e.*, the large amount of hydrogen chloride produced per quantum of light absorbed), (2) by the fact that kinetic equations based upon the chain mechanism adequately describe the reaction velocity and (3) by experiments showing that the reaction can be initiated in the dark by the introduction into the reaction mixture of hydrogen or chlorine atoms from some outside source. There is good reason to believe that hydrogen atoms are produced by an electric arc discharge in hydrogen gas, and that chlorine atoms are produced in the reaction between sodium vapour and chlorine. If the products from either of these reactions are rapidly introduced into a mixture of hydrogen and chlorine, the formation of hydrogen chloride is initiated.

Reaction kinetics has provided much evidence to show that many reactions either in the gas phase or in solution proceed by chain mechanisms.

Heterogeneous Reactions.—Heterogeneous reactions include the solution of solids in solvents, and the reverse process, the crystallization of solids from solution. The reaction of metals with acids and problems of corrosion are part of the subject of heterogeneous reactions. However, by far the majority of the research on heterogeneous reactions is devoted to heterogeneous catalysis (*e.g.*, reactions between gases or liquids catalyzed by solids, etc.). For example, finely divided iron greatly accelerates the rate at which nitrogen and hydrogen unite to form ammonia. Recent studies have shown that iron adsorbs nitrogen in such a fashion as to activate it (by a reaction analogous to the formation of iron nitride); the hydrogen subsequently reacts with the adsorbed nitrogen. Although heterogeneous reactions of this sort are of considerable theoretical and practical interest (*see* ADSORPTION; CATALYSIS) the present article is devoted largely to a consideration of homogeneous reactions.

Enzymes.—Almost the earliest chemical reactions known are the fermentations by which sugar is converted to alcohol or vinegar (fermentation) or lactic acid (souring of milk). These and similar reactions occur in the presence of living organisms, such as yeasts, fungi, etc. In 1897 E. Büchner discovered that, in the fermentation of sugar, the function of the living yeast is to produce a catalyst for the reaction. He destroyed the yeast cells by grinding them with sand. The filtered juice, although it contained no living organisms, nevertheless rapidly converted sugar to alcohol. The complex organic catalysts produced by living cells are called enzymes; those so far investigated in detail have proved to be proteins or protein complexes.

The chemistry of enzymes (*q.v.*) is actively under investigation. The structure of these complex catalysts is partly known, but the mechanism of their action is incompletely understood. Part of the catalytic efficiency of enzymes arises from their ability to adsorb their specific substrates (the compounds whose reactions are accelerated) onto the enzyme molecule, and thus bring them into proximity with the catalytic groups of the protein. Possibly the cooperation of several such catalytic groups, working in concert and in intimate contact with the substrate, may account for the remarkable catalytic efficiency of enzyme systems.

Extensive investigation by a variety of methods (reaction kinetics, isotopic tracers, isolation of intermediates, spectroscopy, etc.) has shown that the fermentation of sugar is a complex process in which many enzymes take part. Similarly, enzyme systems convert starch to sugar, and sugar to alcohol; others hydrolyze proteins into a mixture of amino acids; still others (in conjunction with nucleic acids) synthesize proteins in the body. Enzymes are responsible for the conversion (by a form of combustion) of sugar to carbon dioxide and water, and for the storage, utilization and liberation of metabolic energy. The accelerating effect of some of these enzyme systems is enormous. For example, one part of beef catalase can be detected in 25,000,000 parts of water by the acceleration it produces in the decomposition of hydrogen peroxide. Since the mechanism of enzyme action is unknown, and since the kinetics of enzyme action differs considerably from the kinetics of reactions accelerated by ordinary catalysts, direct comparisons are difficult and likely to be inaccurate. As a rough first approximation, however, catalase is about 10,000 times as active a catalyst as is an equal weight of ferrous ion in catalyzing the decomposition of hydrogen peroxide, and urease is about 10,000 times as active (at 20° C. and in neutral solution) as is an equal weight of sodium hydroxide in accelerating the hydrolysis of urea. These catalysts are thus very much more effective than any so far originated by chemists.

Explosions.—Chemical explosions are rapid reactions which are strongly exothermic; that is to say, these reactions are very rapid ones which evolve large quantities of heat. The hot gases formed in the chemical reaction, or the air heated by the energy released, produce a region of high pressure near the site of the explosion. This region of high pressure travels outward through the air in the form of an explosion wave which usually causes much of the destruction resulting from the explosion. (*see* COMBUSTION; EXPLOSIVES). It is of interest to inquire what are the necessary conditions, and what are the possible mechanisms for a reaction which consumes many pounds of material in (say) 10^{-5} seconds. There are two well-known types of mechanism for explosions: the chain branching mechanism and the thermal mechanism. The latter type was suggested by van't Hoff, the former by N. N. Semenov; examples of both types have been discovered.

The theory of the chain-branching mechanism is that, during the early stages of a chain reaction, more chains are initiated per unit time than are terminated. The most spectacular example of an explosion caused by chain branching is the fission of atomic nuclei, such as occurs in atomic bombs. Here the disintegration of a particular sort of uranium, U^{235} (or of plutonium), is initiated by neutrons, but, in the disintegration, neutrons are also produced. (*See* ATOMIC ENERGY; ISOTOPE; NUCLEUS.) If exactly one neutron were produced from each disintegrating nucleus of U^{235}, a chain reaction analogous to the reaction between hydrogen and chlorine would result. In fact, however, more than one neutron is produced by each nuclear disintegration; the average number is probably about two. An equation for the atomic disintegration is

$$U + n \longrightarrow I + Y + 2n \qquad (22)$$

where U, n, I and Y are the symbols for uranium, the neutron, iodine, and yttrium, respectively. (Other elements besides iodine and yttrium are also produced in the disintegration; the principles involved are, however, the same.) The faster the reaction proceeds, the more rapidly are neutrons produced and the more rapidly does the reaction rate increase. Since the disintegration of the uranium is accompanied by a large evolution of energy, the reaction is an explosion.

The second type of explosion mechanism is the thermal one. Most chemical reactions are carried out under conditions such that the heat evolved (or absorbed) by the reaction is taken away (or supplied) by the surrounding medium. If, however, a highly exothermic reaction is carried out under conditions such that the heat is not carried away by the surroundings, the reaction mixture must become hotter. At the more elevated temperature, the rate of the reaction is much greater; the rate of heat evolution, therefore, becomes much greater also, and the reaction mixture rapidly becomes still hotter. Such a reaction must necessarily lead to an explosion. The question whether a particular exothermic reaction will lead to an explosion is thus largely a question of the conditions under which the reaction is carried out. If the reaction can be made to proceed at such a rate that the heat lost to the surroundings per unit time is small compared with the heat input caused by the chemical reaction during the same interval, a thermal explosion ensues.

Reactions of Isotopes.—In general, the reaction rates of compounds which differ only in that they contain different isotopes of the same element are identical within experimental error. When, however, one of the lighter elements is involved, this need not be the fact. A compound which contains atoms of C^{14} (radioactive carbon) may react at a rate which differs appreciably (*e.g.*, by 6%) from that of a compound identical except that it contains only normal carbon atoms. The rate of reactions of compounds containing deuterium (heavy hydrogen) frequently differs from that of the corresponding compounds of light hydrogen by factors between 5 and 8; even larger factors (and of course smaller ones) have been observed. These large differences in rate, which may

occur when a bond to a hydrogen atom is formed or broken, arise from an effect (zero-point vibrational energy) predicted by quantum mechanics (*q.v.*). Although a discussion of the theory of this effect is out of place here, the phenomenon is proving a most useful tool in investigations of reaction mechanisms.

Fast Reactions.—A number of techniques have led to the determination of the rates of reactions which occur at every collision (or at nearly every collision) of the reaction partners. Since faster rates of chemical change cannot be envisioned (*i.e.*, since molecules cannot react without first colliding) these methods allow the study of reactions at one limit of the entire spectrum of possible speeds. Some of these methods depend upon advances in electronic technology; in particular, rapid-scanning oscilloscopes have permitted measurements of reactions which occur in as little as 10^{-9} seconds (M. Eigen). For example, the rate of combinations of oppositely charged ions in solution (NH_4^+ and OH^-, H_3O^+ and OH^-, H_3O^+ and $SO_4^=$) has been followed by conductometric and other techniques; the rates approach the maximum calculated for such processes in solution. Similarly, in the gas phase, rates have been measured for reactions (*e.g.*, the combination of methyl "radicals") which occur with nearly every collision.

The Collision Theory.—In the theory of reaction kinetics as so far presented, several difficulties have been noted. The present section is devoted to a discussion of these difficulties and the methods of avoiding them; a knowledge of physical chemistry on the part of the reader is assumed.

The ratio of the rates of a forward and of the corresponding reverse reactions gives an approximate expression for the equilibrium constant of the reaction in question, as shown for a special case by equation (13). In the more general case, an analogous treatment of the reaction

$$mA + nB + pC + \ldots\ldots \rightleftarrows gR + hS + iT + \ldots\ldots \qquad (23)$$

leads to equation (24).

$$\frac{(R)^g(S)^h(T)^i\ldots\ldots}{(A)^m(B)^n(C)^p\ldots\ldots} = K_c \qquad (24)$$

The ratio of concentrations on the left side of equation (24) is obtained even if the kinetic equation for the reaction is a complex one. For example, if the reaction is catalyzed, the catalyst concentration appears in the expression for the rate of both the forward and the reverse reaction; it thus cancels out in equation (24). Careful inspection shows that other possible complexities are likewise of no effect on K_c. But equation (24) is nevertheless not precisely correct. The true equilibrium expression (*see* THERMODYNAMICS) is defined in terms of the "activities," not the concentrations, of the reactants and reaction products. Although in dilute solutions the concentration of any substance closely approaches its activity, the two functions are by no means identical. (An analogous statement applies to gases at low pressure.) It is therefore clear that the law of Guldberg and Waage, although approximately correct, is not and cannot be uniformly valid.

The difficulty noted cannot be avoided by the assumption that reaction rates are proportional to activities rather than to concentrations; this assumption has been proved false by investigations of the rates of ionic reactions. The ratio of the activity of any substance to its concentration defines its activity coefficient. The activity coefficients of ions depend upon the ionic strength of the solution in which they occur (*see* SOLUTIONS: *Solutions of Electrolytes*).

This ionic strength is a function of the concentrations and of the charges on all the ions present; in dilute solutions the activity coefficients of all ions decrease with increasing ionic strength. But the rates of reactions between two ions of like charge increase with increase of ionic strength; only for reactions between ions of opposite charge do the rates (like the activity coefficients) decrease with increasing ionic strength. Thus the rate of a reaction is not proportional to the "activities" of the reactants; it has already been shown that only as a first approximation is this rate proportional to the ionic concentrations.

The difficulty, at least insofar as ionic reactions are concerned, has been resolved by the assumption that reaction rates are proportional not to concentrations or activities, but to the number of collisions per second between the reacting ions. The number of collisions between charged particles should not be strictly proportional to the product of their concentrations. Let W be the ratio between the number of collisions among the reacting ions and the product of the ionic concentrations. Then, because of interionic effects, W should increase with increasing ionic strength for reactions between ions of like charge, and decrease with increasing ionic strength for reactions between ions of unlike charge. This predicted behaviour is in qualitative agreement with the anomaly in ionic reaction rates already cited.

J. A. Christiansen's calculation (1924) based on the theory of P. Debye and E. Hückel, accounts quantitatively for the observed rates of ionic reactions in dilute solution. Further, although the forward and reverse rates, taken separately, are not proportional to the activities of the reactants and reaction products, the expression obtained by setting equal the rates of the forward and reverse reactions (corrected to account for interionic effects) yields the thermodynamic equilibrium expression in terms of activities, not concentrations. How this happens is made clearer in the consideration (*see* below) of the activated-complex theory of reaction velocity. In general, it has been assumed that consideration of the actual number of collisions always leads to corrections for the law of Guldberg and Waage, such that the dynamic and thermodynamic equilibrium constants become equal.

It should be pointed out that interionic and other forces not only affect the change in the number of collisions with change in concentration; they also affect the actual number of collisions per unit time. Thus, in a reaction between two positively charged ions, forces of electrostatic repulsion lower the number of collisions far below that computed from the kinetic molecular theory. Furthermore, it is not true that every collision between reactant particles moving, relative to one another, with a velocity greater than the critical one, u_0, leads to chemical change. There must also be a definite orientation of the molecules with respect to one another at the moment of collision. This consideration holds especially for complex molecules, which may be capable of reacting only at one end. The collision theory is thus considerably less precise than may at first have appeared.

Application of kinetic molecular theory to a simple bimolecular reaction (*e.g.*, the decomposition of hydrogen iodide) leads to equation (25), which relates the rate constant, k, with u_0, the minimal velocity at collision, necessary for reaction.

$$k = \frac{4N^2d^2}{c^2}\sqrt{\frac{\pi \mathbf{k}T}{m}}\left(1+\frac{mu_0^2}{2\mathbf{k}T}\right)e^{-mu_0^2/2\mathbf{k}T} \qquad (25)^3$$

Here N molecules of effective diameter d and weight m are present at a concentration of c moles per litre and at an absolute temperature T. The symbol e is the base of the system of natural logarithms, and $\mathbf{k}$ is Boltzmann's constant, 1.38×10^{-16} ergs/degree. If the values of k are experimentally determined for a series of temperatures, the values of both u_0 (the minimal velocity of one molecule relative to another required for effective collisions) and of d (the effective diameter of the particles) can be determined. The difficulties previously discussed then appear as anomalously large or small values of d^2. That is to say, when the reacting particles attract each other, the cross sections of the molecules (proportional to d^2) which are "effective" for collisions, will be large compared to these cross sections as determined by other methods; conversely, when the particles repel one another, or when a preferred orientation is necessary for reaction, the "effective" cross section will be small. The latter condition holds (although not to a marked degree) for the hydrogen iodide reaction.

An alternative description of the reaction process may be obtained by computing a collision number on the basis of the best available estimates for molecular cross sections and by replacing equation (25) by (27), to which it is approximately equivalent.

$$k = PZe^{-Q/RT} \qquad (27)$$

[3] If the two molecules which react are not identical, this expression must be somewhat modified. Among other modifications, the reduced mass μ replaces m. If the masses of the two molecules in question are m_1 and m_2, then the reduced mass μ is defined by equation (26).

$$1/\mu = 1/m_1 + 1/m_2 \qquad (26)$$

Here Z is the "normal" collision factor, P is the "probability" factor defined by equation (27), and Q is the activation energy which does not differ greatly from $\frac{1}{2}Mu_0^2$, where M is the molecular weight of the substance in question. The difficulties of the collision theory are then contained in the factor P, and the problem of obtaining precise agreement between theory and experiment is reduced to that of computing P correctly.

One additional aspect of collision theory deserves attention. Some reactions (as previously stated) are of the first order. Such reactions would seem to be independent of collisions. In what way can these reactions be correlated with collision theory? Some first-order reactions probably cannot be so correlated. The disintegration of radium is strictly of the first order; the rate of the reaction depends upon changes in the radium nucleus, which are unaffected by collisions of the molecule as a whole. But in ordinary chemical, as opposed to nuclear, reactions, the energy necessary for reaction is probably acquired by the decomposing molecule through previous collisions.

The Activated-Complex Theory.—An alternative general theory of reaction kinetics is formulated in terms of the so-called "activated complex" (S. A. Arrhenius, J. N. Brönsted, N. Bjerrum, H. Eyring). In this theory, it is assumed that all the reactants are in pseudoequilibrium with an activated complex, X,

$$mA + nB + pC + \ldots\ldots \rightleftharpoons X \longrightarrow \text{products} \qquad (28)$$

which in turn decomposes to give the reaction products. The activated complex X is not a true molecule; it is merely a stage in the process by which the reactants become the reaction products. Hence, the activated complex is not in true equilibrium with the reactants. The activated-complex theory, however, is founded on the assumption that the concentration of the activated complex may be computed just as if it were a real, stable chemical compound. The rate of reaction is then the product of the concentration of X multiplied by the rate at which it decomposes. This rate can be computed by the general methods of quantum mechanics (*q.v.*); it is the same for all activated complexes, regardless of the materials out of which they have been formed. For a reaction such as (23), the activated-complex theory leads to equation (29)

$$v = \kappa \frac{kT}{h} K^*(A)^m(B)^n(C)^p \ldots\ldots \frac{\gamma_A{}^m \gamma_B{}^n \gamma_C{}^p}{\gamma_X} \qquad (29)$$

where k is the Boltzmann constant, h is Planck's constant, K* is the equilibrium constant for the formation of the activated complex (its decomposition into the reaction products being disregarded), and $\gamma_A, \gamma_B, \gamma_C, \ldots\ldots \gamma_X$ are respectively the activity coefficients of the reactants and of the activated complex. The constant κ is called the transmission coefficient; it is usually nearly unity. When the activated-complex theory is used to describe a reversible reaction, a distinction must be drawn between the activated complex formed from the reactants and that formed from the reaction products. The two complexes, although structurally the same, differ with respect to the materials from which they have been formed and into which they are decomposing. Unless the distinction in question is made, the theory is self-contradictory.

Equation (29) contains γ_X, the activity coefficient for the activated complex. Although this coefficient cannot be measured (since the activated complex is not a stable entity) it can be estimated for the complexes which occur in ionic reactions. The charge on the activated complex must be the sum of the charges on the reactants; furthermore, the charge on an ion, as a first approximation, determines its activity coefficient. Equation (29) correctly predicts the rates of ionic reactions; it leads to results identical with those obtained by Christiansen. Although in particular instances the collision theory may be more convenient to apply than is the activated complex theory, or vice versa, the two always lead to the same results; they are, in essence, two different languages in which the same phenomena may be described.

At equilibrium, the rates of the forward and reverse reactions are equal. When two rate expressions analogous to (29) are used, an equation (30) is obtained from which the activity coefficient of the activated complex and the transmission coefficients have been eliminated.

$$\frac{(R)^q(S)^h(T)^i \ldots\ldots (\gamma_R)^q(\gamma_S)^h(\gamma_T)^i \ldots\ldots\ldots\ldots}{(A)^m(B)^n(C)^p \ldots\ldots (\gamma_A)^m(\gamma_B)^n(\gamma_C)^p \ldots\ldots\ldots\ldots} = K \qquad (30)$$

Here K is the true thermodynamic equilibrium constant, expressed in terms of activities (concentrations multiplied by activity coefficients).

The pseudoequilibrium constant, K*, of equation (29) is related to the free energy of activation, ΔF^*, the heat of activation ΔH^*, and the entropy of activation ΔS^*, by equation (31).

$$-RT \log_e K^* = \Delta F^* = \Delta H^* - T\Delta S^* \qquad (31)$$

The heat of activation, ΔH^*, corresponds roughly with the energy of activation, Q, of the collision theory; the entropy of activation, ΔS^*, may be roughly related to the logarithm of the "probability" factor, P, of equation (27).

The thermodynamic concept of entropy has been interpreted, through statistical mechanics, in terms of molecular vibrations. Likewise, entropy of activation can often be interpreted in terms of the geometry and of the estimated vibrational frequencies of the activated complex.

The application of the activated-complex theory depends upon the computation of the pseudoequilibrium constant, K*. Thus, the kinetic problem is replaced by a thermodynamic one, and all the powerful tools of thermodynamics and of statistical mechanics become immediately available for its solution. It is possible in principle (always) and in practice (occasionally) to calculate the rate of a chemical reaction without the use of any experimentally determined kinetic data. The difficulties reside principally in the selection of appropriate constants for the activated complex. For the reaction between a hydrogen atom and a hydrogen molecule (which has been investigated by the use of ortho- and parahydrogen and of deuterium), the absolute reaction rate has been computed by methods related to the activated-complex theory (E. Wigner). Modern investigations, with molecular beam techniques, seek to determine the individual vibrational and rotational quantum states of gaseous molecules and to understand in great detail the geometry and energy of the reaction process. Most reactions are, however, too complex for complete mathematical solution by methods now known.

(F. H. WR.)

READE, CHARLES (1814–1884), English novelist, journalist, and dramatist, worked enthusiastically for the theatre but is remembered chiefly for his novels; he was an ardent reformer, but won his greatest fame with his historical romance, *The Cloister and the Hearth* (1861). He was born on June 8, 1814, at Ipsden House, near Ipsden, Oxfordshire, and entered Magdalen College, Oxford, in 1831. He graduated in 1835, was elected Vinerian fellow in 1842, took the degree of doctor of civil law in 1847, and was vice-president of his college in 1851, but treated the position as a sinecure. Meanwhile he had studied for the bar and was called in 1843 but never practised. He made various tours in Europe and, although he kept his fellowship and his college rooms for life, lived mainly in London. He had a great interest in violins, was himself a fair performer, and, as a young man, was an active partner in a Soho violin business.

Reade spent the greatest part of his energy and money writing and staging plays. He wrote 40, including translations, adaptations, and collaborations with other authors. Like much English 19th-century drama his plays are crippled by lurid spectacle, sensational incident, crude characterization, and conventional stage morality. His greatest success in the theatre was *Drink* (1879), an emasculated version of Émile Zola's *L'Assommoir*, but the liveliest and most readable is the early *Masks and Faces* (1852), a mildly witty comedy about the 18th-century actress Peg Woffington, written in collaboration with Tom Taylor. Reade found a loyal friend in Mrs. Laura Seymour, the actress, who was his housekeeper from 1856 until her death in 1879.

Reade also wrote short stories and 14 novels which made his name and fortune. He was sensitive to injustice and inhumanity and many of his works exposed contemporary social abuses. *It Is Never Too Late to Mend* (1856) attacked conditions in prisons and *Hard Cash* (1863) exposed the ill-treatment of mental patients, especially in private asylums; *Put Yourself in His Place* (1870) dealt with the terrorist activities of trade unionists; and the melodramatic *Foul Play* (1868), written with Dion Boucicault (*q.v.*), revealed the racket in "coffin ships" and helped to sway public opinion in favour of the safety measures proposed later by Samuel Plimsoll (*q.v.*). But the very intensity of Reade's indignation against these abuses led him to exaggerate his facts, and his work was also damaged by the "stage eye" with which he regarded characters and situations, and by his naïve belief that the use of "hard facts" in a novel ensures artistic truth. He sometimes introduced into his novels people who had temporarily claimed the public's attention, such as William Austin, governor of Birmingham jail when Edward Andrews hanged himself there in 1853. Austin appears as the brutal Hawes in *It Is Never Too Late to Mend.* Unlike Mrs. Gaskell, Reade was, in fact, a "sensation" rather than a serious "social" novelist. But he amassed much information for his propaganda novels and was sincere in his attempts to do good. He often pleaded his causes in pamphlets and in magazine and newspaper columns, and made a praiseworthy attempt to establish international stage rights and copyright.

The Cloister and the Hearth, although not a propaganda novel, cost him much research. It related the adventures of the unknown father of Erasmus. Acceptance of human tragedy and ability to present it dramatically and sympathetically make this the best of Reade's novels. Next in merit comes *Griffith Gaunt* (1866) in which Reade explores a marriage relationship and the passion of jealousy, but the book is spoiled by a conventional ending.

He was a systematic writer and tried to compensate for his lack of imagination by industry. He was quarrelsome and litigious and could be malicious toward those he disliked. Yet he was capable of great generosity and would work unceasingly for a favourite cause. Like Charles Dickens a reformer, he lacked Dickens' fertile imagination and ready invention, his sense of comedy and control of language. Reade's strength as a novelist is arresting narration of exciting action; his greatest defect is reliance upon prejudices and conventions because of his inability to observe human behaviour. He died in London on April 11, 1884.

(S. M. SM.)

READING, RUFUS DANIEL ISAACS, 1ST MARQUESS OF (1860–1935), British lawyer and statesman, lord chief justice of England from 1913 to 1921 and viceroy of India from 1921 to 1926, was born in London on Oct. 10, 1860, the second son of Joseph Michael Isaacs, a fruit importer. He was educated at University College School, London, and in Brussels and Hanover. He served in the merchant navy for two years from the age of 16 and then worked on the London Stock Exchange without success. He turned in 1884 to the law, where he found his life's work. He qualified as a barrister in 1887 and his knowledge of city affairs helped him to build a large and rewarding practice. Entering the House of Commons in 1904 as Liberal member for Reading, from which he later took his title, he held that seat until 1913 when he was made lord chief justice (Oct. 22, 1913).

He was appointed attorney general in 1910 and two years later was given a seat in the Cabinet, the first attorney general to have received such promotion. In the same year he was involved with other ministers in a bitter party controversy which arose out of their transactions in the shares of the American Marconi Company (of which his brother, Godfrey, was managing director), shortly after the English Marconi Company had received a contract from the British government. By a party majority a select committee of the House of Commons acquitted the ministers of all charges of corruption. Reading's tenure of office as lord chief justice was marked by humanity and by the establishment of the principle that the Court of Criminal Appeal should be a real court of revision. He presided over the trial of Sir Roger Casement, the Irish patriot, who in 1916 was convicted of treason and hanged.

During World War I, his main service was to assist in securing the money Britain needed and in strengthening Anglo-American relations. He was president of the Anglo-French Loan Commission to the United States from September to October 1915, and in September 1917 he returned there for a brief period, with John Maynard (later Baron) Keynes as his economic adviser, on a mission to bring some order into Britain's war spending. From January 1918 to May 1919 he was ambassador extraordinary and high commissioner to the United States. By the time of this appointment he had been raised three stages in the peerage—Baron Reading of Erleigh (1914), Viscount Reading (1916), and earl of Reading (1917).

He resigned the office of lord chief justice in 1921 and was appointed viceroy of India at a time when that country was in a state of nationalist ferment. A dyarchy had been established by the Government of India Act of 1919 as a step toward independence, but it had not brought tranquillity (*see* INDIA-PAKISTAN, SUBCONTINENT OF: *History*). The system was rejected by the Swaraj (self-rule) movement of educated Hindu and Muslim opinion, and Mohandas K. Gandhi persuaded millions of Indians to boycott Western goods and institutions by passive resistance. They resented the humiliations suffered by their fellow countrymen elsewhere in the British Empire, and the ruthless suppression of the Amritsar Rebellion (April 1919) had driven Indians to a state of dangerous anger. Reading had only limited success in trying to gain Indian assent to British policy. He imprisoned two Muslim leaders, the brothers Mohammed and Shaukat Ali, in 1921. He sought reconciliation with Gandhi but had him prosecuted in March 1922 for incitement to civil disobedience. Some form of self-government was established in most of the provinces and there was an approach to cooperation in the central legislative council, but the constitution broke down completely in the Central Provinces and was suspended in Bengal with a return to autocratic government.

Reading tried to conciliate Muslim opinion when he cabled in February 1922 to the secretary of state for India, Edwin Samuel Montagu, suggesting that the terms of the Treaty of Sèvres (1920) should be eased for the Turks. The proposal was published by Montagu without the authority of the Cabinet, and it helped to bring Lloyd George's pro-Greek policy to an end. It also led to Montagu's resignation.

Reading's term as viceroy ended in April 1926, and on his return to England he was made a marquess (May 7, 1926), the first commoner to be so elevated since the duke of Wellington. He was secretary of state for foreign affairs (August–November 1931) in J. Ramsay MacDonald's National government. Reading died in London on Dec. 30, 1935.

See 2nd Marquess of Reading, *Rufus Isaacs, First Marquess of Reading, by His Son,* 2 vol. (1942–45).

(J. F. B.)

READING, a county and parliamentary borough and the county town of Berkshire, Eng., 38 mi. (61 km.) W of London by road. Pop. (1961) 119,937. Area 14.2 sq.mi. (37 sq.km.). Reading is an important junction of railways running west from London and south from the Midlands, and the Kennet and Avon Canal, to Bath and Bristol, and the Thames afford it connections by water. It lies on the Kennet River near where it joins the Thames. All the ancient churches are restored: Greyfriars Church, formerly monastic, was completed early in the 14th century and after the dissolution of the monasteries served successively as a town hall, a workhouse, and a jail, being restored to its proper use in 1864; St. Mary's was rebuilt in 1551 from the remains of a nunnery founded by Aelfthryth in expiation of the murder of her stepson Edward the Martyr; St. Laurence's is a Perpendicular building with Norman and Early English features; St. Giles's was much damaged during the siege of 1643 by the parliamentary forces and is almost wholly rebuilt. Public gardens occupy most of the

site of the Benedictine Abbey.

A University College was opened in 1892 and affiliated to Oxford; its success led to the gathering of an endowment fund and it became an independent university with a charter in 1926. Its researches into agriculture, horticulture, and dairying are of special importance. The National Institute for Research in Dairying, established in 1912, is part of the university. At the grammar school, founded in 1485 and now occupying modern buildings, Archbishop Laud (a native of Reading) was educated. There is also a bluecoat school (1656) now just outside the borough at Sonning. The municipal museum, besides an art gallery and other exhibits, includes Roman relics from Silchester (*q.v.*) and finds from the Thames.

Reading early became a place of importance. In 871 the Danes encamped there, and in 1006 it was burned by Sweyn. It consisted of only 30 houses at the time of the Domesday survey. It is thought that a fortification existed there before the Conquest, and Stephen built a masonry castle which Henry II destroyed. On the foundation of a Benedictine Abbey in 1121, the town, hitherto demesne of the crown, was granted to the Abbey by Henry I. Henry VIII converted the Abbey, whose church was among the largest in the country, into a palace and it was destroyed during the Civil War. From the 12th until the 16th century, Reading's history was that of the struggle as to rights and privileges between the Abbey and the merchants' guild. A 16th-century account of the merchants' guild shows that many trades were then carried on, but John Leland says the town "chiefly stondith by clothing." By the 17th century the trade had begun to decline; the bequest of the clothier John Kendrick (d. 1624) did little to revive it, and it was greatly injured by the Civil War. In the 18th century the chief trade was in malt.

The first town charter is that of Henry III (1253), confirmed and amplified by succeeding sovereigns. The governing charter until 1835 was that of Charles I (1639), incorporating the town under the title of the mayor, aldermen, and burgesses. The market, chiefly held on Saturday, can be traced to the reign of Henry III; four fairs granted by the charter of 1562 are still held.

Reading is an agricultural centre with famous nursery gardens. Its biggest and best-known industry is biscuit manufacture, but there is much business in printing, iron foundries, engineering works, malting, and brewing. The sale of corn, cattle, and flour is carried on extensively, and there are pottery and brick works, together with riverside boatbuilding yards. The parliamentary constituency of Reading returns one member to Parliament.

READING, a city of southeastern Pennsylvania, U.S., the seat of Berks County, is located on the Schuylkill River, 58 mi. NW of Philadelphia. Population (1960) city, 98,177 (a 10.2% decrease from 109,320 in 1950); standard metropolitan statistical area (Berks County), 275,414 (255,740 in 1950). (For comparative population figures *see* table in PENNSYLVANIA: *Population.*)

History.—In 1748 Reading was laid out and surveyed at the great ford on the Schuylkill. The plans were supervised by Thomas Penn, who insisted on the large open square, Penn Common, for market purposes, as was common in England. He named the town for the seat of Berkshire, Eng., the ancestral home of the Penns. Four years later, when Berks County was created, Reading became the county seat. It was incorporated as a borough in 1783, with a population of 2,100, and was chartered as a city in 1847.

Though there were many Germans among the first settlers they were not politically minded and control of local affairs remained in the hands of the English. As a result of the Revolutionary War, the German element in Reading and elsewhere in Pennsylvania began to assert itself and eventually elected three governors from Reading and Berks County. As early as the spring of 1775 two companies of infantry (mostly Germans) left the district for service under Gen. George Washington near Boston. Reading served as a depot for supplies and as a manufacturer of cannon and it maintained a prison camp for the Hessians captured at the Battle of Trenton. The thrifty Pennsylvania Germans hired out some of the Hessian prisoners in their charge. During the American Civil War, Reading was the first to send a military unit to defend the national capital when Abraham Lincoln called for troops. The Ringgold light artillery, largely locally recruited, was later named the "First Defenders."

The local citizens are still proud of their predominantly Pennsylvania-German heritage, which they seek to keep alive at the widely attended annual Pennsylvania Dutch folk festival at nearby Kutztown.

Industrial Growth.—From the earliest days the making of iron and steel was important. In this area the first cold-blast furnace in America was set up and the first steel was commercially produced in Pennsylvania. At the middle of the 19th century Berks County had more iron- and steel-producing plants than any county in the U.S. The prosperity of Reading's primary iron and steel production continued until the upper Great Lakes ore replaced the use of Pennsylvania ore. Reading made the adjustment by shifting to the fabrication of iron and steel. The opening of the Schuylkill Canal to Philadelphia in 1824 (abandoned in 1922), the Union Canal to Lebanon and Middletown on the Susquehanna in 1828 (abandoned in 1880), and the building of the Philadelphia and Reading Railroad in 1838 (extended to Pottsville in 1842) greatly stimulated industrial growth, as did the building of the Pennsylvania Railroad to Reading in 1884.

An interesting feature of Reading's industrial history was the sudden mushrooming of safety-bicycle manufacturing to satisfy the fad of the 1890s. When the bicycle boom passed much hope was held out for automobile manufacturing. From 1900 to 1912 Charles E. Duryea manufactured a durable car that won a number of speed and endurance tests but did not sell well. The Reading Steamer, produced from 1900 to 1903, was a novel machine that did not catch the fancy of the buying public.

The decline of primary iron and steel manufacturing and the blasted hopes of the bicycle and the automobile business were offset by the development of the textile and hosiery industry by two German technicians, Ferdinand Thun and Henry Janssen, around 1900. Other Germans built textile and hosiery factories and gave the city a national reputation.

Reading became an important retail and wholesale trading centre. It is located in the midst of a rich agricultural, dairy, and industrial county and ranks third industrially in the state, with about 700 industrial establishments in the city and its suburbs. These include railway shops and plants producing builders' hardware, foundry products, hosiery machinery, clothing, optical goods, chemicals, dairy products, and pretzels. One of the largest full-fashioned hosiery mills in the world is located there, as are also an extensive single-unit foundry and a huge brick-burning kiln.

Skilled craftsmen form a large proportion of the population and union organizations are strong in the community, which has a tradition of unionism and socialism.

Reading was the second city in the U.S. to elect a socialist government. "Jim" Maurer was for many years nationally known as the leader of a moderate brand of socialism. (In contrast to the usual moderation, during the railroad strikes in 1877 ten men were killed and scores seriously wounded.)

The hosiery business, which once employed more than half the wage earners of Reading, has declined, but the city anticipated the slump and in the 1950s and 1960s stimulated new industries and the growth of old industries to take up the slack.

Education and Cultural Activities.—The public-school system comprises evening and summer schools in addition to the usual kindergarten through senior high school. A unique feature is the ownership by the school district of an extensive museum and art gallery, both of which are thoroughly integrated into the public school work at all levels. The butterfly collection and the collection of Carboniferous Age insects are nationally recognized. Pennsylvania State University, the University of Pennsylvania, and Temple University maintain extension centres and institutes at Reading. Albright College (Evangelical United Brethren; founded in 1856), a four-year liberal arts college, is also located there. The county historical society has a valuable collection of ancient fire-fighting equipment. Both the symphony orchestra and the Ringgold band are among the oldest in America.

Parks and Historic Sites.—Mt. Penn, to the east of the city, rises to an elevation of 1,140 ft. and is the centre of a park system

of more than 2,000 ac. The Duryea Drive winds to the immense Chinese pagoda on the top. Penn Common (50 ac.) is still a popular recreational area in the heart of the city. The anchor of the battleship "Maine" rests there.

Among the many historical landmarks in Reading and its environs are the Conrad Weiser Farm, Hopewell Village National Historic Site, the Daniel Boone homestead, and the sites of early forts and furnaces. (L. A. Gr.)

READING. This article deals with the history of reading, methods of teaching children to read, and the important benefits derived from good reading habits. For other aspects of the subject *see* Illiteracy; Education, History of.

Reading is an important facet of communication and an essential aid to personal welfare and social progress. In the first two decades of the 20th century, the teaching of reading was largely limited to training in oral word perception with emphasis on reading aloud and repeating to the teacher the details stated by the author. Though this approach is still dominant in many countries, in others, including the United States, reading is considered to be primarily a process of securing and reacting to ideas recorded in written or printed symbols. To read, either silently or orally, one must recognize words, know their meanings, understand the ideas expressed by the author, sense the mood and tone of the selection, evaluate the accuracy of the ideas, and use or apply them.

As suggested by the foregoing statements, reading is a highly complicated activity that may involve all of the mental processes used in thinking.

HISTORY

The history of reading cannot be told apart from that of writing, which it interprets. Primitive man made pictures to communicate ideas, and there is evidence that the pictures were quite similar throughout the world. They were made with pointed flintflake on stone, bone, horn, and every other conceivable material. When these pictographs proved inadequate to represent all of the ideas and feelings the writer wished to express, they were partially replaced by ideographs. Later, parts of pictographs were substituted for the whole; for example, the three-toed imprint to represent a wild turkey. Thus drawings came to be more standardized and to serve as symbols of the ideas to be expressed. Some of the early pictographs were combined and simplified to be more easily written. Instruction in reading was not necessary because the meanings of the pictographs were self-evident (*see* Pictography).

In the course of time man has developed many types of written languages. The first in the order of their historical development are called word-concept characters or ideograms, each representing a specific concept or idea. These have been used in China for 3,000 years or more. A great disadvantage of the use of word-concept characters is that one must learn thousands of them before he can read widely.

In his efforts to overcome such difficulties, man discovered that language consists of sounds which can be represented by written characters. He also found that such characters can be combined in many ways to represent all the words of language. The first character of this type has been called a syllabic-sound character. As implied by its name, each such character represents the sound of a syllable. Thus the word *notation* would be written with three characters. The number of characters used in writing corresponds to the number of different syllables in a language. Syllabic-sound characters are used in Japan in combination with Chinese characters.

The most highly refined and useful type of character that man has invented is the letter-sound character. Each letter represents one or more basic sounds of a language. Through the use of an alphabet of about 26 letters, it is possible to write all the words of a language. The use of letter-sound characters is most effective when each letter always represents a given sound. Of the various types of alphabets in current use the Latin, or Roman (Modern European), is by far the most popular.

When printing was done by hand on materials that were scarce, only the clergy and persons of wealth or high position learned to read. With the invention of paper in Europe, followed shortly by the first printing presses, printed reading matter became available to a larger segment of the population (*see* Printing: *The History of Printing*). By the beginning of the 19th century the ability to read was so highly valued that increasing numbers of children attended school.

As the need for teaching all children and adults to read and write has become more urgent during the 20th century, many countries have taken steps to simplify and improve their traditional written and printed characters, or to adopt new ones. In 1929, for example, the Turkish government decreed that the Roman alphabet should be substituted for the Arabic, which had been used in that country for centuries. The rapid spread of literacy following this change supplied clear evidence of its great practical value. A more radical step was taken soon after the organization of the People's Republic of China in 1949. The new government appointed a Committee on Research on the Chinese Written Language to select and simplify a basic set of Chinese characters for immediate use. A minimal number of most frequently used characters was identified and has been widely taught. Information for the masses is written in this basic vocabulary. Long-term aims are the development (for permanent use) of a phonetic alphabet for writing a common Chinese language and the translation of all Chinese literature into the alphabetical characters.

Following the development of letter-sound characters, it was assumed for many centuries that the first step in learning to read was to master the names of the letters. Children memorized the names of the alphabet in order, then combined two or more letters to form syllables. For example, meaningless syllables (such as *ab, ac, ad, ib, ic*) were practised for mastery. Later the syllables were combined to form both meaningful and nonsense words. This, popularly known as the ABC method, employs the so-called synthetic approach, in which the parts are combined to make the whole. In spite of many protests from those who advocated an analytic approach, the alphabetic method of learning to read was used predominantly from early Greek and Roman times until late in the 19th century.

According to U.S. reading specialist Nila B. Smith there was vigorous protest against the ABC method about the middle of the 19th century. Although the ABC method continued in use for many years, the protests stimulated experimentation in teaching reading in two directions. One focused on a somewhat different synthetic approach, the phonetic method, in which the word is recognized by its sounds rather than by its letter-names. However, it is necessary for young children to memorize the sounds of the letters, then blend them together to form syllables, and blend the syllables into words before they begin to read. During the early period of experimentation, complicated systems of printing evolved for the purpose of representing several sounds made by a single letter, especially the vowels. A great deal of ingenuity was used to help beginning pupils associate the sounds with the printed letters.

The analytic approach, as advocated by Horace Mann and others, involved teaching the visual recognition of whole words before any attention was given to either the letter-names or letter-sounds. In experiments teachers discovered that pupils learned to recognize a word as quickly as they could a letter. Thus the word method, often called the sight method, of teaching reading gradually gained sanction in many schools. Later, the sentence, representing a unit of thought, was introduced first: the words were then learned as parts of the sentence and the letters were learned last as parts of known words. Both the synthetic and analytic approaches have strong proponents. But many teachers, recognizing the limitations of an exclusive use of either approach, have joined them in numerous combinations.

Research.—Scientific studies of the reading process have altered the entire concept of the task involved in teaching reading. Research was greatly facilitated by the development of instruments for studying the behaviour of the eyes during reading. Until late in the 19th century, it was assumed that the eyes moved in continuous sweeps across the line of print. Studies revealed,

however, that the eyes move from left to right in a series of short quick movements with pauses between movements. Between 1900 and 1920 elaborate cameras were developed to study the behaviour of the eyes and, with the advent of motion-picture cameras and films, a great deal of new information was secured about the process of reading.

Eye-movement photographs revealed many pauses too brief to be seen except on film. The pauses, called fixations, are made to take in one or several words and probably to modify the ideas conveyed by earlier words in the selection. The number of words or letter-spaces seen at a single fixation is called the span of recognition. A regressive movement occurs when the eyes return to look again at words previously seen. The eyes move swiftly from the end of one line to the beginning of the next. Speed of reading can be determined by relating the length of a filmed record of eye movements to the number of words read. The beginning reader makes many long pauses and many regressive movements. As he learns to read, the movements of the eyes become rhythmical and the number of fixations and regressions is substantially reduced. This discovery led to experimentation in training the eyes to move rhythmically, but it was found that efficiency in eye-movements results not from such training but from maturity in the use of reading skills and habits.

Concurrent recording of the movement of the eyes and the pronunciation of the words revealed that the eyes move ahead of the pronunciation. Among good readers, the separation is greater at some times than others. Difficult materials reduce the eye-voice span. Poor readers tend to look at each word and pronounce it, resulting in inexpressive oral reading.

One of the major findings of eye-movement photography revealed that the processes of oral and silent reading were different, and that children and adults read different materials in different ways. These new insights motivated extensive research which led to an expanded definition of reading and eventually to the conclusion that many facets of reading must be taught. One of the resulting changes was a shift in emphasis from teaching oral reading to teaching silent reading. A second change came as a result of the discovery that teaching the literal meaning of sentences and paragraphs did not ensure the learning of the attitudes and skills involved in interpreting, evaluating, and applying the ideas secured.

Tests.—Another important tool for studying reading was the standardized test. Tests both of intelligence and of achievement appeared before 1920 and thereafter were used increasingly both in laboratories and in schools. Reading tests supplied a yardstick that enabled teachers to measure progress of individual pupils from year to year, and to see the wide range of individual differences among pupils in a given class.

Modern standardized reading tests may be classified as survey tests, survey tests with diagnostic features, and diagnostic tests. Survey tests usually yield two scores: vocabulary, which combines the ability to recognize words and to know their meanings; and comprehension, including understanding sentences and paragraphs. Survey tests with diagnostic features include a number of subtests, require a longer time for administration, and provide greater insight into the different aspects of competence in reading. These two types of tests can be administered to groups. Some diagnostic tests may be given to groups, but most of them require individual administration. They may measure aptitude of visual and auditory discrimination, motor control, language facility, and the like. Others appraise sight vocabulary, word attack skills, and ability to associate visual and auditory symbols. More advanced tests permit analysis of several aspects of comprehension, including literal and nonliteral meanings, and assess rates of reading easy and difficult materials.

Informal tests often are used in the classroom, in addition to the standardized tests. The pupil is frequently asked to read orally and/or silently sample pages from a graded set of readers. Checklists of characteristics of particular difficulties are used to supplement the informal inventory.

As new insights have been obtained, the reading curriculum has been expanded. At the same time, it has become clear that certain skills and abilities should be taught prior to others, and a sequence has been worked out and generally accepted.

STAGES IN LEARNING TO READ

Research has shown that although pupils of a given age differ in their attainments, all pupils go through similar stages in learning to read. The major difference lies in the rate at which each pupil masters successive stages. Examples may be cited at any level, but at first grade (age six in the United States) some pupils are not yet ready to read while others read as well as the average second- or third-grade pupil. By the fourth grade, a few pupils are reading at first-grade level, others at second, several at third, and many at fourth. In addition, a number will have attained scores at fifth-, several at sixth-, and a few at seventh- and eighth-grade levels. Such ranges in reading achievement have led school personnel to examine carefully the stages in reading which different pupils are achieving. Usually these stages are not clear-cut; each merges gradually into the succeeding one.

The first stage is usually called reading readiness, or preparation for learning to read. This begins, as M. Monroe and B. Rogers, in *Foundations for Reading* (1964), point out, at birth. Early experiences, language development, learning to listen to and enjoy books read aloud, and learning to work with others, to follow directions, and to complete appropriate tasks are examples of basic requisites for reading provided by the home. Furthermore, the values placed on reading for information, self-improvement, or relaxation by parents become models for their children to follow. The nursery school and kindergarten add to this preparation, especially by extending the children's range of experiences and strengthening areas of weakness for particular pupils (*see* ELEMENTARY EDUCATION; PRE-ELEMENTARY EDUCATION). Physical, mental, social, emotional, and language maturity of the average pupil of six years is considered optimal for success in beginning reading. Those who are not judged ready for formal instruction usually receive additional preparation in first grade (see *Reading Readiness,* below). An interest in looking at books and asking about words is usually acquired by the end of the first stage of growth.

In the second stage, children learn to read very simple materials. In the United States, children usually begin by learning a few sight words, and gradually master approximately 300 by the end of the first year. Basic skills in unlocking the meanings of unfamiliar words are introduced, such as the use of context clues and the beginning sounds of words, and a few become fairly well established. By the end of this period children should be reading simple books independently and with enthusiasm.

The third stage is characterized by rapid progress in mastering an increasing sight vocabulary and in acquiring skills in unlocking unfamiliar words. Children learn to read for different purposes and in different content areas, such as science and social studies. They learn to use reading as a means for learning, to satisfy their curiosity, and for pleasure.

The fourth stage is characterized by the acquisition of more mature reading interests and tastes. During this period all of the previously learned abilities are refined and enhanced. Word recognition is gradually increased; knowledge of word meanings is extended and precision of meaning is acquired. Understanding or ability to interpret grows as the reader secures a better background against which to evaluate what he reads. He is able to apply new knowledge acquired from his reading to assist him in adjusting his attitudes and behaviour. His reading interests become broader and, in worthwhile areas, more intensified. He begins to become what William S. Gray described as the mature reader.

READING READINESS

A few pupils are already reading when they enter the first grade but the great majority require from three weeks to several months of preparation, the continuation of the reading readiness that has gone on since birth.

During the first half of the 20th century, several experiments showed that reading readiness will not always result from merely

waiting until children are older chronologically. Instead, many of the necessary abilities can be taught. Hence direct teaching for children who are not ready to read is generally recommended.

Physical readiness involves good vision and hearing. Frequently, the school nurse tests school entrants and asks parents to have any visual or hearing defects corrected so that pupils will be free to learn more readily. Motor coordination also seems to be important, especially eye-hand coordination, and the habit of moving the eyes and hands from left to right. Most children learn to colour pictures, to cut on lines, to draw and paint, to string beads, to construct objects from clay; these and other manual activities are encouraged to improve motor coordination.

The notion of intellectual readiness suggests that a minimum mental age is necessary to begin formal reading. Research reports are not in agreement on this factor, except that retarded pupils often require more systematic and longer periods of preparation for reading. Two factors often included in evaluating mental maturity are visual and auditory perception. Visual perception is necessary so that the child can take in and remember an entire word and the letters that are combined to make words. Training in visual perception involves matching similar forms, selecting one that is different from others, and finally noting similarities and differences in the letters themselves. Children who lack auditory discrimination are unable to hear the differences between words that are similar in sound, such as *bit, bet,* and *bat,* even though there is no hearing loss. Auditory discrimination is strengthened by teaching pupils to listen closely to the sounds that make words.

Language readiness is acquired when pupils speak clearly and can use several sentences in correct order. They must understand the ideas about which they talk and be able to use the words which they will learn to read. One way in which many teachers help develop language readiness is by having the pupils help plan class activities, such as trips to the post office or fire station, and then encouraging them to talk about these experiences. Children are also encouraged to talk about their personal experiences. As soon as the teacher is certain that a pupil is familiar with the ideas needed, can use the words, can express himself in sentences, and can follow the sequence of a story, this phase of his readiness is completed.

Personal readiness involves the ability to work and learn with other children, to give sustained attention for a short period, to follow directions, to complete a task, and the like. Frequently, activities that a child considers to be play are planned by the teacher to improve his personal readiness to read. In addition, pupils need to know about books, to learn to handle and enjoy picture books, and to develop a lively curiosity about what the words say. Teachers help pupils by reading to them, showing pictures, asking the children to illustrate stories, encouraging them to examine labels on common objects, and by other similar activities.

Reading readiness is measured by tests, in part, and also is estimated by the teacher. The child who is pressed into formal reading before he is ready often fails to make satisfactory progress and forms a dislike of reading because of his frustration.

METHODS OF TEACHING READING

Children who are ready to read may first learn to recognize words based on some experience they have had which is interesting and exciting. For example, a class trip to a farm, a park, or a zoo may be discussed. As the children talk, the teacher prints their story in two or three sentences on the chalkboard. Various pupils may then read back to the class the story they have composed, while the teacher slides her hand or a pointer along the line. Additional experiences can be described with many of the same words and introduce new ones. Gradually the sentences are divided into phrases, and finally the words themselves are identified. After a few words are learned in this fashion, children are usually given a pre-primer. In this small book, they learn to recognize words from clues provided by pictures and from class conversations about the pictures. When the group has mastered the words of the pre-primer, the children then continue with the primer, the first reader, and succeeding books. Each book provides additional practice in recognizing words already taught and in identifying new words. Questions about what is read maintain the interest in getting meaning from print. When the pupil can recognize a number of words at sight, the beginning sounds are taught by using several words that begin alike. As each sound that makes up known words is learned, pupils are encouraged to use this knowledge to figure out the pronunciation and meaning of unknown words. Thus the pupils learn the phonic elements and how to use them in reading. The initial sounds are used along with a guess based on the meaning of an entire sentence. The latter is called use of context, or meaning, clues. The names of the letters are learned when they are needed to spell words, and the order of the alphabet is learned when pupils must use the dictionary.

In some countries, especially where the phonetic elements of the language are regular, the sounds of the letters are taught first and the sounds are then combined in different ways to make words. The phonic or synthetic approach is used in a few schools in the U.S. In England, J. C. Daniels and Hunter Diack have developed the "phonic word method." Beginning with words, the sounds of the letters are taught as a part of the words. The words are introduced with emphasis on the sounds as signals of order of pronunciation. The aim of both the analytic and the synthetic approach is to teach pupils that the abstract signs on the page convey meaning. Furthermore, whether the first instruction is by sight, phonics, or the phonic word method, a vocabulary of commonly used words should soon be recognized quickly by sight.

Experiments in the use of the Initial Teaching Alphabet (i.t.a.) in teaching beginners to read began in England in 1960 and in the United States in 1963. This alphabet, developed by Sir James Pitman, grandson of Sir Isaac Pitman of shorthand fame, consists of 44 symbols, each representing one of the 40 phonemes (sounds) of the English language. The symbols are the traditional Roman alphabet (minus "q" and "x") augmented by 14 symbols that resemble two letters joined together (as "ae" and "ee") and 6 special symbols representing the other phonemes. Early results of the experiments were encouraging, with high rates and levels of achievement and low rates of failure reported, and schools in Great Britain, the United States, and Canada adopted i.t.a. on a trial basis. Optimism was tempered by caution against regarding i.t.a., which is a learning tool, as a complete answer to problems of teaching reading.

PITMAN'S INITIAL TEACHING ALPHABET, WITH ITS 44 SYMBOLS AND WORDS ILLUSTRATING THE SOUNDS THESE SYMBOLS REPRESENT

During the primary grades, children learn to recognize words which are familiar to them and which they use in conversation. By the middle grades, unfamiliar words are met and pupils learn to get the meanings through the context and by use of a glossary or a dictionary. Generally, teachers introduce some new words by discussion or by audio-visual aids. Gradually pupils become independent in arriving at the meanings of words. Vocabulary is taught not only in the reading period but also in all subjects that require reading. Best results are achieved when children and young people have direct rather than incidental instruction to expand their vocabularies.

Comprehension and interpretation of printed and written materials are taught from the early school grades on through high school, and sometimes in college. At first the materials used are simple and within the realm of experience of the pupils. Gradually, the materials become more difficult, less familiar, and even abstract. The student must make a variety of adaptations. In literature, for example, he may read one selection to get the general idea; another to sense the mood and tone of the author; and

another to study the characters and plot. Poetry may be read orally for the beauty of the language. Thus, comprehension and interpretation may include reading to get the main idea, to get details, to follow directions, to arrive at conclusions, to interpret the author's ideas and feelings, to evaluate for accuracy or bias, or to appreciate the literary expression and content.

As word recognition, understanding of word meanings, and comprehension improve, rate of reading usually increases. The first-grade pupil reads silently and orally at about the same rate. By third grade the average pupil begins to read silently at a rate more rapid than when he reads orally. Rate of reading for the mature adult should vary with the difficulty of the material and the purpose for which it is read. For example, a person might read a novel for sheer pleasure at 300 words per minute. The same person might read an article dealing with politics at 200 words per minute. He might read at only 100 words per minute a technical article on the atom bomb. Thus, the mature reader has many reading rates.

Teachers encourage pupils to read large amounts of materials of interest to them and at an appropriate level of difficulty. Thus, children learn to read widely for information, to solve problems, and for pleasure. At the upper school levels young people are guided by teachers and librarians to better literature, and to sources designed to help them solve their personal and social problems. Schools and colleges aim to develop refined reading tastes and permanent reading interests.

CONDITIONS AFFECTING READING

Many factors are important in promoting maximum efficiency and comfort in reading. Miles A. Tinker concluded from extensive research and a review of other studies that no reading should be done with less than five footcandles of light. Furthermore, the minimum light in the schoolroom should be ten footcandles. The paper from which one reads should have a dull finish to avoid reflection and glare. Black print on a white background appears to offer the greatest contrast and therefore to be more readable than any other combination of colours.

Many of the investigations of type size in relation to reading have been done with adults. Some work, however, has been done with children, and in 1955 Cyril Burt recommended the following sizes in (type face) points: for children under 7 years, 24; for 7 to 8 years, 18; for 8 to 9 years, 16; for 9 to 10 years, 14; for 10 to 12 years, 12; and for 12 years and over, 11. Furthermore, Burt and his colleagues concluded that the words should be well spaced out for young children. Studies with adults show a close relationship between type size and preference as to length of line. Adult readers prefer a line near three inches in length. Although D. G. Paterson and M. A. Tinker recommended any modern type face, preferably one that borders on boldface, Burt reported other preferences for children. Those under 12 years preferred Old Style Antique, while Imprint, Plantin, or Times New Roman were preferred by children over 12 years.

READING INTERESTS

Many studies have been made of the reading interests of school children, young people, and adults. The results show that pupils differ widely at each age and grade level. Certain common trends, however, have been noted. In the primary grades, children are usually interested in familiar experiences and enjoy stories about children of their own ages, and about animals. They prefer narrative to other types of materials.

In the preadolescent period, the majority of boys exhibit interest in adventure, descriptions of "how-to-do-it," hero tales, hobbies, and science. At the same period, girls' interests turn toward home and family life and fantasy, with slight interest in adventure. Girls often choose boys' books, while boys do not like girls' books. Adolescent boys are interested in reading about mysteries, sports, and recreational activities. On the other hand, girls frequently turn to romances and stories of teen-age problems. The reading interests of adults are varied and complex. Douglas Waples and Ralph W. Tyler concluded that "international attitudes and problems" and "personal hygiene" were the only two topics of interest to all the groups they studied. Otherwise, the reading interests of adults vary with sex, years of schooling, occupation, age, and environment. Ease of securing reading materials is also related to interests. Newspapers and magazines are read more frequently than books.

Personal Reading.—The amount of reading done by pupils can only be estimated by indirect evidence. The number of children's books published and library circulation figures are two indicators of the amount of personal reading done for information and pleasure. Between 1925 and 1965, the number of new books and new editions for children increased about 400%. Likewise, the total number of books published and sold increased by over 100%. Similarly, library circulation of children's books showed marked increases during a comparable period. The percentage of children who read books voluntarily increases rapidly through the primary and middle grades until by the junior high school years (ages 12–14) virtually all pupils read some books. But fewer high school students read books and they read fewer books than in the earlier years. Beginning about 1940, studies showed an increase in the number of newspapers and magazines read by children and youth. This increase may have been due to the fact that newspapers and magazines for different age groups were becoming available at that time. Comic books have universal appeal to children in the middle grades. In the upper grades and high school, there is a gradual decrease in the proportion of children reading them as well as in the number read.

At all ages most children prefer and read more fiction than nonfiction. Young children read children's books until ages 12 to 15, when they gradually change from the juvenile and teen-age stories to adult fiction.

Benefits and Effects of Reading.—The emphasis on the teaching and use of reading reflects the confidence that reading contributes to personal and social development, either positively or negatively. Widespread adult concern over children's reading of crime and thrill comic books bears witness to the negative effects ascribed to reading. On the positive side, studies summarized by William S. Gray indicate that reading influences the extent and accuracy of information as well as the attitudes, morale, beliefs, judgments, and actions of readers.

The child who learns to read readily soon finds a new avenue of exploration. He is more likely to be successful in all school subjects if he reads well. In addition, he has a leisure-time activity in which he can live vicariously. He can travel to other countries and meet children of other cultures in books. He can experience otherwise unobtainable thrills of adventure in far-off times and places. He can become increasingly independent in pursuing his hobbies. For example, a boy can read the directions for putting together a model airplane, or an adolescent girl can follow a recipe to make a dessert for her party. Thus reading becomes a tool for learning, a means for satisfying curiosity, and a pleasant leisure-time activity.

Bibliotherapy, which is the personal interaction between the reader and literature, has been shown to be one method of therapy for some maladjusted persons. Librarians report progress in the adjustment of young people when books dealing with adolescent problems and activities are read and discussed.

RETARDED READERS

Some pupils grow physically and mentally at the same rate as their age-mates but make less than average progress in reading. Others move through one or more stages of reading growth but fail to progress further. Those who are capable of continued reading improvement but who fall behind their capacities are classified as retarded readers. Confusion in identifying retarded readers is not uncommon. For example, all of those who rank below the norms of a standardized reading test are often so classified. However, since the norm of the test represents the middle score of all pupils who took the test, half of every typical group of pupils is expected to rank at or below the norm. A large proportion of those whose scores are below the norm are children whose IQ's are below average or who are slow in all aspects of learning. A few have extreme physical limitations such as partial

deafness or partial blindness. But the pupils whose mental abilities exceed their reading achievement by one or more years and who appear to be capable of reading at a level much beyond their achievement are commonly regarded as retarded readers. Depending on the school and the magnitude of the difference between mental age and reading achievement that has been adopted as a standard, from 5 to 20% of school children may be classified as retarded readers.

Many group intelligence tests depend heavily upon reading ability; as a result, bright pupils who read poorly are often classified as dull. Individual intelligence tests, or, in some instances, group tests of intelligence that require no reading ability, are likely to give fairer estimates of capability to read for these students. Some authorities suggest that, for retardation to be regarded as significant, reading achievement should be below capacity by one half year in the primary grades, one year in the middle and upper grades, and two years in high school and college.

Reading retardation, as described above, has been attributed to visual difficulties, emotional disturbances, home and family problems, and school methods improperly adapted to individuals. Hearing loss, glandular insufficiency, and poor general health have been found among poor readers. Minimal brain damage, or neural immaturity, also have been associated with reading retardation in some cases. Most pupils who are severely retarded in reading are found to have several difficulties in varying combinations. In most instances, an examination by a reading specialist can identify the factors interfering with reading progress; the pupil may then be referred to proper specialists for correction. Difficulty in reading, particularly if due to brain damage, is known medically as dyslexia.

Retarded readers may be found at all school levels and in adult life. The most severely retarded, or those reading below the fourth-grade level, usually have been unable to learn to recognize words. One of three approaches to remedial instruction, the sight approach, often begins by choosing a short, exciting selection written as simply as possible. The student reads orally. Each word that is not recognized is written or typed on a card, the configuration and the parts of the word are noted carefully, and finally the word is read again in the original context. Frequent reviews of each word in different contexts are needed for mastery.

The phonetic approach begins by teaching the sounds of the letters, either in isolation or in words. As the sounds are associated with the letters, they are blended to form the whole word. New words made up of familiar sounds may then be pronounced. Gradually these words become familiar and are recognized at sight. The number of words in the English language which require exceptions to common generalizations becomes a handicap if this method is used exclusively.

The kinesthetic method is initiated by having the learner dictate a short story, or perhaps only a sentence, which is written on the chalkboard by the teacher. Individual words not recognized by sight are written with crayon on a large sheet of paper. Then the pupil traces each word as he pronounces it, syllable by syllable if necessary. He continues to trace and pronounce the word until he can write and pronounce it from memory. At the next lesson, he reads a typewritten edition of his story, again tracing any words that he fails to recall. As the student's sight vocabulary increases, he finds that he can recall certain words without tracing, and gradually this procedure is eliminated.

One of the foregoing approaches may be adopted as the primary method but the other two may be needed at particular stages of progress. Although these remedial methods emphasize learning to recognize words, this step is only a means to the end of understanding the ideas presented by print. Experience reveals that progress is more rapid if words are used in varying contexts as soon as possible, and practice is given in using words to secure meaning.

Many students with disabilities in reading have learned to recognize words but they may be uncertain about word meanings or may lack one or several of the skills necessary in understanding literal and nonliteral text. Others may read too slowly or too rapidly and be unable to adjust their speed of reading to their purpose and to the difficulty of the materials. In most instances disability in vocabulary, comprehension, or rate of reading may be attributed to faulty instruction and insufficient practice. Therefore, remedial instruction follows the pattern of sound developmental procedures, beginning with materials at the level at which the learner can succeed and progressing systematically and rapidly to establish reading competence.

School children who are retarded only a year or so in reading may be taught in their classrooms by a competent teacher. Schools in the United States frequently have a reading consultant or a remedial teacher to assist the classroom teacher. Children who are more seriously retarded are often taught by a remedial reading teacher who instructs small groups three to five periods each week. If the remedial teacher is unsuccessful or if no specialist is available in the school system, individual children may be referred to a reading clinic if one is located nearby.

Retarded readers are unable to compete with their peers in school; hence they lose confidence in their intellectual abilities. At the same time, both parents and teachers press them for better performance. As a result many poor readers become emotionally disturbed. Young people who do not read adequately often leave school as soon as possible, but they are quite handicapped. Few jobs are open to nonreaders and they are not eligible for promotions to positions that require reading. They find it impossible to read a menu in a restaurant, to follow maps for travel, to determine the particular movie playing at any time, or to correspond with family and friends. Thus reading disability interferes with academic, personal, and professional adjustment. Fortunately, the great majority of retarded readers can make rapid improvement, especially if their difficulties are found and corrected early in the school years.

Some clinics use instruments to aid in helping retarded readers. The tachistoscope is one frequently employed. It is a slide- or strip-film projector that projects words or phrases on a screen. A cameralike shutter controls the amount of time a word or phrase is exposed to view. Generally the exposure-time ranges from 1 to $\frac{1}{100}$ sec. It is used to increase speed of word recognition and the number of words seen at one glance. The value of this instrument, in comparison with good teaching, has not been demonstrated conclusively.

Several other instruments are used for pacing speed of reading. They are designed so that a shutter or light moves over the page of a book at a fixed rate. The rate can be increased gradually, thus pushing the reader to read more rapidly. Many authorities agree that at least as good results can be obtained through proper teaching without the instruments, which are unnatural to the reading situation. The major value of most instruments appears to be that of motivating the pupil.

It seems likely that most children and adults can learn to read better and more rapidly if they want to do so. Reading is best improved by motivated practice with a clear purpose in mind.

REAL ESTATE, a nonlegal term often used to mean real property (*see* REAL PROPERTY AND CONVEYANCING, LAWS OF), but more frequently to describe the business of developing, managing or merchandising of land and its buildings. A real-estate agent in the United States is comparable to an estate agent in England. In some places real estate refers to urban land as distinguished from farms or farm agents. In most states of the United States a real-estate agent must be licensed, often after

passing an examination. Real-estate boards in the U.S. attempt to impose standards of conduct on persons engaged in the business. Such a board is comparable to societies in England such as the Chartered Surveyors Institute, Estate Agents Institute, and the like.

See ESTATE AND HOUSE AGENTS; *see* also references under "Real Estate" in the Index. (A. DM.)

REALGAR, a mineral species consisting of arsenic monosulfide and occurring as crystals of a bright red colour, usually occurs with ores of silver and lead in mineral veins. Realgar has been produced commercially in Europe and Asia and has been mined in small quantities in the United States. It has been used as a paint pigment and as a depilatory in tanning and for producing a brilliant white fire in pyrotechnics, but has largely been replaced by artificially prepared arsenic sulfide. The composition is AsS. It crystallizes in the monoclinic system and there is a perfect cleavage parallel to the plane of symmetry; hardness is 1.5–2, specific gravity 3.55. On exposure to light the crystals crumble to a yellow powder. The other native arsenic sulfide, As_2S_3, is known as orpiment (*q.v.*). (L. J. S.; X.)

REALISM (Latin *res*, "a thing"), a term used in several senses in various disciplines.

In metaphysics realism has two quite distinct meanings. First, in the history of scholasticism, it is used to designate the doctrine that universals (*see* UNIVERSAL) have real existence: extreme realism in this sense maintained that universals, such as goodness, justice, roundness, redness, humanity, and so on, exist independently of the particular objects in which they are perceived, and that these objects are real only insofar as they participate in the universal; moderate or mitigated realism maintained that the universals really exist *in* the particular things in which they are perceived by the mind as forming their common nature. Conceptualism (*q.v.*), on the other hand, maintained that universals exist only in the mind, whereas Nominalism (*q.v.*), in its extreme form, would deny universals altogether. The second metaphysical use of the term realism is to designate the contention that the objects of sense perception have real existence outside the perceiving mind, as opposed to Idealism (*q.v.*). (*See* further KNOWLEDGE, THEORY OF.)

In ethics, realism is occasionally used to mean conduct based on considerations of practical advantage, without regard for ideal goodness or equity.

In literature, the term realism may be loosely applied to any writing that seeks to portray life exactly as it is (or, in histories and historical novels, is believed to have been), without embellishment or idealization. In a more restricted sense, it is applied to the style of such novelists as Gustave Flaubert (*q.v.*; and *see* NOVEL), in opposition both to Romanticism and to Naturalism; the latter tended eventually to emphasize the more sordid aspects of life that the realists had not gone out of their way to stress.

REAL PRESENCE: *see* TRANSUBSTANTIATION; EUCHARIST.

REAL PROPERTY AND CONVEYANCING, LAWS OF. The division of property into "real" and "personal," like so much in Anglo-U.S. law, can only be explained historically. In early law, property was deemed real if the courts would restore to a dispossessed owner the thing itself, the *res*, instead of merely giving compensation for its loss. All interests in land fell within this category, with the exception of leaseholds, which were at first regarded more as mere contractual rights than as interests in land (*see* LANDLORD AND TENANT). Indeed, not until late in the 13th century could a dispossessed leaseholder recover even damages against any save his lessor, and when by the end of the 15th century it was finally decided that he might recover the land itself, the classification of leaseholds as personal property had become too firmly established for it to be altered. Thus if today a testator dies leaving all his realty to R and all his personalty to P, the reason for his leasehold's passing to P instead of to R lies in a rule that ceased to exist more than four centuries ago.

This article, which is concerned with the law of real property and its transfer from person to person in Great Britain and the United States, may be outlined as follows:

I. ENGLISH LAW

Real property is traditionally classified as either corporeal or incorporeal. A right is corporeal where it is accompanied by physical possession of land and incorporeal where it is not. Thus a fee simple in possession is corporeal, whereas a fee simple subject to a life interest is incorporeal, and so are rights over the land of another, such as easements (*e.g.*, a right of way) and profits *à prendre* (*e.g.*, a right to pasture cattle).

For the purposes of the common law, land includes any type of soil, even if covered by water. A plot of land is deemed to stretch indefinitely upward and to the centre of the earth downward. Buildings and other structures, and things growing in or on the land, normally pass automatically with it. The produce of any piece of land becomes the owner's by accession. Objects merely resting on the land do not form part of it; if let into the soil, however, or otherwise firmly fixed to it, or to something else which is let into it or fixed to it, they do form part of it and are called "fixtures." In certain cases persons entitled to possession of land only for a limited period, such as lessees or tenants for life, may remove, on quitting, any fixtures they have brought onto the land. In other cases they may receive from the freeholder compensation for improvements they have made; these are sometimes called "betterment," as also are works outside the property which increase its value, such as the improvement of access by the making of a public road. Statutes may oblige the landowner to contribute to the cost of such betterment works. Crops produced annually by the labour of the cultivator are termed "emblements" and constitute an exception to the rule that growing crops always pass with the land. They are personal property and so may pass separately from the land on the owner's death. On a sale, however, they pass with the soil unless specifically excluded.

Certain words have acquired a customary meaning when describing the extent of land transferred. "Messuage" means a dwellinghouse together with its outbuildings, and "curtilage" is any courtyard or garden belonging to it. "Dwellinghouse" itself may also be used with that extended meaning. "Farm" includes the farmhouse and the land held with it. "Water" gives the right to both water and fishing but not to the subsoil beneath the water. "Pool" includes both the water and its bed. Owners of land bounded by a river or by the seashore automatically acquire any gradual and imperceptible accretions to the land (alluvion) due to recession of the water.

1. Tenures and Estates.—The main distinguishing features of

the English law of real property are the two doctrines of tenures and estates. The basis of these doctrines is the rule (which in theory still exists) that all land is owned by the crown and that subjects may hold land as tenants but cannot own it. There is no allodial land (*i.e.*, land that is the absolute property of the owner) in England. In days when land and its rents and profits constituted most of the tangible wealth of the country, the whole social organization was based upon tenants holding land from a lord in return for various services. However varied the services may have been originally, they became to some extent standardized, and each set of services became known as a tenure, for it showed how the land was held.

The doctrine of estates was directed to the length of time for which the land was held. Each estate could exist in land of any tenure. The two main estates were the fee simple, which endured as long as the tenant or any of his heirs survived (whether his descendants or not), and the life estate, which ended with the tenant's death. The statute *De Donis Conditionalibus* of 1285 (13 Edw. I. c.1) created a third estate, the fee tail, which endured so long as the tenant or any of his descendants lived. A variant, called a conditional fee, was an estate which would subsist until the happening of some uncertain event. Provided that the event chosen to terminate the fee was lawful and did not offend the rule against perpetuities, anything could be selected; *e.g.*, the marriage of a certain person or the destruction of a certain tree. The event could be one which might never happen, such as that members of a family should cease to be lords of a certain manor. Such an estate could be transferred, subject always to the fact that the happening of the condition would bring it to an end.

All these types of fee exemplified the central principle that what a subject could own was not the land itself but merely an estate in that land. This conception of an abstract estate rather than the corporeal land being the subject matter of ownership was a remarkable and distinctive achievement of early English legal thought which contributed greatly both to the triumphant flexibility of the English system and to its undoubted complexity. The description of that system as "an ungodly jumble," a phrase usually attributed to Oliver Cromwell, is understandable but misleading. (*See* ESTATES, ADMINISTRATION OF.)

2. Capacity to Own and Deal with Land.—With certain exceptions, any person is entitled to own and transfer land. The seven principal categories of persons whose rights are or used to be restricted are the following:

Infants.—Since 1926, infants have been unable to hold legal estates in land. Any attempt to convey a legal estate to an infant creates a settlement for the purposes of the Settled Land Act, 1925, with some person of full age entitled to exercise the powers of the tenant for life. The Infant Settlements Act, 1855, authorizes the Chancery Division of the High Court of Justice to sanction certain marriage settlements including dealings with real property made by infants.

Married Women.—Formerly, a wife needed her husband's concurrence to deal with land belonging to her; but the Married Women's Property Act, 1882, and subsequent legislation, equated her position with that of other adults. (*See* HUSBAND AND WIFE, LAWS CONCERNING: *Property and Liabilities.*)

Bankrupts.—Land belonging to a person who is adjudged bankrupt remains vested in him, but the power to deal with it is transferred to his trustee in bankruptcy or to the official receiver in bankruptcy. Public registration of bankruptcies ensures that they come to the notice of potential purchasers of land.

Corporations.—All corporations, except those created by royal charter, formerly needed a "license in mortmain" to authorize them to hold land (*see* MORTMAIN). The license was normally given automatically by the statutes authorizing incorporation, as, *e.g.*, to trading limited companies, the commonest form of corporation. In the absence of a license in mortmain, land was liable to be forfeit to the crown. The law of mortmain, and with it the necessity for licenses, was abolished by the Charities Act, 1960. A corporation, however, still must be given power to hold and deal in land by its instrument of incorporation, and without this dealings will be *ultra vires* and void. Upon the liquidation of a company for insolvency, its land remains vested in it, but the powers of the board of directors to dispose of it are exercisable only by the liquidator.

Insane Persons.—The property of persons incapable, by reason of mental disorder, of managing their affairs is administered under statutory powers. The court appoints a receiver to deal with a patient's property as directed by the court. If a mentally disordered person himself deals with his property, the transaction will, if fair, be voidable, but not void. To prevent its being enforced against him, he would have to prove that the other party knew him to be of unsound mind.

Felons.—Until the enactment of the Forfeiture Act, 1870, persons convicted of treason, murder, and other felonies forfeited their lands to the crown. They are no longer placed under this disability.

Aliens.—Aliens formerly were not allowed to hold land in England, but since 1870 nationality has been no bar to land ownership. In time of war, however, enemy aliens cannot make valid contracts and so are barred from dealing with their land for value. *See* also ALIEN.

A. HISTORY THROUGH THE 19TH CENTURY

1. Before the Conquest.—The principal features of English land law before 1066 were (1) liberty of alienation of such land as could be alienated (mainly or entirely bookland; *see* ANGLO-SAXON LAW: *Folkright and Privilege*), either *inter vivos* or by will; (2) publicity of transfer by enrollment either in the shire book or church book; (3) equal partition of the estate of a deceased person among his sons, and, in default, among his daughters; (4) cultivation mainly by serfs of various degrees, owing rents in money or labour; (5) variations by custom, tending to become uniform through the similarity of approach of local courts; (6) the *trinoda necessitas—i.e.*, the tenant's obligations of military service, repair of bridges, and maintenance of fortifications. The ownership of land was the basis of political privilege, conferring territorial jurisdiction on the landowner. In relation to folkland, this jurisdiction became vested in the king as ultimate arbiter, and in many cases he delegated powers to the great landowners.

2. The Formative Period.—*The Common Law.*—The main effect of the Norman Conquest upon land law was the integration of a system already largely feudal. The rule that all land was owned by the crown was firmly established, and although there might be any number of subinfeudations and so any number of mesne lords, there was always a complete chain of seigniory between the occupying tenant and the king as lord paramount. Further, tenures tended to become stereotyped. When the full effects of the Conquest had been felt, it was possible to classify tenures with some degree of exhaustiveness. The main division of tenures was into free and unfree.

The three main classes of free tenure were (1) tenures in chivalry (principally grand serjeanty and knight service); (2) tenures in socage (principally petty serjeanty, common socage, burgage, and customary socage, *i.e.*, socage subject to special customs such as gavelkind and borough English); and (3) spiritual tenures (principally frankalmoign and divine service). Grand serjeanty obliged the tenant in person to perform some honourable service for the king, while in petty serjeanty the service to the king was of a nonpersonal nature (*see* SERJEANTY). Knight service (*q.v.*) involved providing military service to the king or other lord, though by the middle of the 12th century this was usually commuted for a payment called scutage (*q.v.*). In common socage (*q.v.*), the principal service was usually agricultural in nature, such as performing so many days' plowing each year for the lord. Burgage (*q.v.*) was a variant of common socage in boroughs, and under gavelkind and borough English (*qq.v.*) the land descended on intestacy to all the sons equally and to the youngest son, respectively, instead of to the eldest son. In addition to the principal service, all these tenures were subject to a number of feudal incidents, such as relief, primer seisin, escheat and, in the case of tenures in chivalry, wardship and marriage. The spiritual tenures were appropriate to ecclesiastical corporations such as bishops or monasteries, their sole obligation being to pray for the souls of

the grantor and his heirs; the number of prayers was specified for divine service and unspecified in frankalmoign ("free alms").

The two unfree tenures were villein tenure (which later was called copyhold; *q.v.*) and customary freehold. The essence of unfree tenure was that although the tenant's services were fixed as to quantity (*e.g.*, as to so many days' work per week), they were uncertain as to quality, so that the lord might set the tenant to whatever type of work he wished.

The Legislation of Edward I.—The first Statute of Mortmain, 1279 (7 Edw. I. St.2. c.13), prohibited the conveyance of land to religious bodies without licence from the crown. This avoided the lord's losing his feudal dues by the land's passing into the "dead hand" of a monastery which was never under age, never died, and could never be attainted. But the two statutes in the reign of Edward I of prime importance to the subject are *De Donis Conditionalibus*, 1285 (13 Edw. I. c.1), and *Quia Emptores*, 1290 (18 Edw. I. c.1); each is still in force, and they may with some justice be regarded as two of the main pillars of the law of real property.

Before 1285, if land was conveyed to "X and the heirs of his body," the birth of heirs of his body was treated as a condition, so that once issue had been born, X was able to convey the whole fee simple and defeat the expectations of his issue. *De Donis* provided that the land should descend to X's issue successively *secundam formam in carta doni expressam*, and on failure of heirs of the body revert to the grantor. This produced a "cut down fee" (*feodum talliatum*). By means of collusive actions known as "fines" and "recoveries," it had become possible two centuries later for a tenant in tail to "bar the entail" (*see* ENTAIL) and obtain a fee simple; but the fee tail remained to provide the foundation for the strict settlement as a means for keeping land in the family. *Quia Emptores* prohibited subinfeudation, the process whereby one tenant granted land to another to hold of the grantor as lord. Thus if after 1290 A granted land to B in fee simple, B's lord would be not A but A's lord. This prevented the growth of the feudal pyramid, but in the course of time most land came to be held from the crown and not from mesne lords.

3. The Growth of Equity.—Uses (or trusts) became fairly common during the 13th century, and early in the 15th century the chancellor began to enforce them (*see* EQUITY; TRUST). By vesting the legal estate in a number of reliable "feoffees to uses," it was possible to avoid many of the rules governing real property, especially feudal burdens such as reliefs and wardships, and the prohibitions against conveyances into mortmain, and devises; for these rules governed only the legal estate and not the equitable interests in the use. Uses were thus employed to subvert the well-settled law and defeat the feudal claims of the lord; and when the lord paramount was Henry VIII and Parliament submissive, legislation intended to destroy uses was inevitable.

4. The Statute of Uses, 1535.—This act (27 Hen. VIII. c.10) converted equitable interests in realty into corresponding legal estates: if A was seised to the use of B, the statute "executed" the use and converted B's equitable interest into a legal estate, A dropping out. This facilitated a simplification in the procedure for transferring a legal estate in land. Previously it was normally effected by "feoffment with livery of seisin"—*i.e.*, a verbal declaration of intention to convey accompanied by the giving of actual possession of the land, symbolized by handing over a twig or a clod of earth. Advantage was now taken of the concept that a vendor who had agreed to sell land was holding it to the purchaser's use. The purchaser's use was executed, vesting the legal estate in him, so that land could be transferred by "bargain and sale" (*i.e.*, a simple contract) without taking possession. As this would also have made a secret transfer possible, the Enrolment of Bargains of Lands, etc., Act, 1535 (27 Hen. VIII. c.16), required the enrollment of all bargains and sales in one of the king's courts. Early in the 17th century a means of avoiding the statute was evolved. V bargained and sold to P a lease for one year; this was outside the statute and gave P a legal lease without publicity or entry on the land. The next day V conveyed the reversion to P by a simple "release" by deed. This "lease and release" remained the normal mode of conveyance until the Real Property Act, 1845, s.2, enabled all land to be conveyed by a simple conveyance by deed.

The Statute of Uses brought greater variety and flexibility to the legal interests in land that could be created. The rules of the common law prohibited a condition being attached to a fee which would end it and pass the land into the hands of a stranger. Upon the termination of an estate for life or of an estate tail, the land had to revert to the donor or his heirs. Equity had allowed other interests to arise by means of the creation of a use in favour of the stranger. These "conditional limitations" now became possible at law when the use was automatically executed. The Statute of Uses was also thought to have abolished the power to devise land, and the resulting outcry produced the Statute of Wills, 1540 (32 Hen. VIII. c.1), which permitted a testator to devise all socage land and two-thirds of land held in knight service. The Tenures Abolition Act, 1660 (12 Car. II. c.24), in effect made all land devisable; it converted tenures in chivalry into common socage, subject to preserving the honourable incidents of grand serjeanty.

5. Development of the Modern Law.—The Statute of Frauds, 1677 (29 Car. II. c.3), provided that certain transactions relating to land should be in writing or evidenced by writing; and in the reign of Anne, the Middlesex and Yorkshire deeds registries were established (*see* TITLE TO LAND). But perhaps the most striking feature of this period was the perfection of the settlement and resettlement as a device for keeping land in the family. The core of a marriage settlement was that the husband (H) was given a life estate, with remainder to his first and other sons successively in tail. The wife was given an annual income by means of rent charges, providing for "pin money" during H's life, and a larger sum by way of jointure after his death. All the children save the eldest son who succeeded to the land were given lump sums of money known as portions, protected by a portions term (a long lease) vested in trustees. When the eldest son attained full age, H persuaded him to join with him in barring the entail and resettling the resultant fee simple on H for life, with remainder to the son for life, and then with remainder to the son's sons successively in tail. The land was thus tied up for another generation. The common law had evolved a rule that it was not possible to create an unbarrable entail, but conveyancers circumvented this by ensuring that no person entitled under the settlement should have an entail unless he was an infant and so incapable of barring it. By these methods, great family estates could be built up by ensuring that the land passed as a whole to each eldest son in turn, and yet provision was made for the other members of the family. One disadvantage of this system was that in the absence of express provision there was no person with power to dispose of any of the land or to grant leases which would be binding after the grantor's death. Often the tenant for life was given a series of express powers, but sometimes these were defective, and in any event their presence made the settlement a document of formidable bulk.

6. The Age of Reform.—In the century after 1830 there were three main groups of statutory reforms; namely, the statutes of 1832 to 1845, the statutes of 1881 and 1882, and the statutes of 1922–25. The two main features of the legislation were (1) to eliminate anomalies and (2) to shorten documents by enacting as law those provisions which had become common form.

1832–45.—The Prescription Act, 1832, achieved a qualified success in providing greater certainty in the law governing the acquisition of easements and profits by long enjoyment, and the Real Property Limitation Act, 1833, reformed the law governing the acquisition of title to land by long possession. The Fines and Recoveries Act, 1833, substituted a simple conveyance for the dilatory and expensive methods of barring entails by fines and recoveries. The Dower Act, 1833, enabled a husband to dispose of land free from his wife's prospective claim to dower (a life interest in one-third of his land) on his death, while the Inheritance Act, 1833, reformed and clarified the law governing the descent of land to the heir on intestacy. The Wills Act, 1837, made many improvements in the law of wills, particularly as to formalities. The Real Property Act, 1845, enabled corporeal here-

ditaments to be transferred by grant; *i.e.*, by a deed. This brought corporeal hereditaments into line with incorporeal hereditaments, which had always been so treated. Although livery of seisin had long been superseded, the fiction of lease and release could now also be abandoned.

1881–82.—The Conveyancing Act, 1881, did much to shorten conveyances by enacting many provisions which formerly had to be set out expressly. But it was the Settled Land Act, 1882, which was the great achievement of this period. It extended some rather timid legislation of 1856 and 1867, and gave to every tenant for life of settled land wide powers of selling, leasing, and otherwise dealing with the land. On such a dealing, the interests of the various beneficiaries under the settlement were "overreached"; *i.e.*, transferred from the land to any capital money, which had to be paid to the trustees of the settlement and not the tenant for life.

B. Property Legislation of 1925

Great changes in the law were made by the Law of Property Act, 1922, most of which, however, was repealed and reenacted before it had come into force. On Jan. 1, 1926, there came into force the unrepealed portions of the act of 1922, together with the Law of Property Act, 1925, the Settled Land Act, 1925, the Trustee Act, 1925, the Administration of Estates Act, 1925, the Land Charges Act, 1925, the Land Registration Act, 1925, and the Universities and College Estates Act, 1925. These acts, often collectively called "the 1925 property legislation," were drastic, far-reaching and wholly successful in bringing the law into accord with modern needs. The main features of this legislation will be taken in turn.

1. Abolition of Unnecessary Historical Survivals.—First, all tenures were in effect converted to common socage, though the honourable incidents of grand and petty serjeanty were preserved. Copyhold was the one tenure which was still of practical importance, and the tenant was required to pay compensation for most of the incidents of any real value which were abolished. Second, the Statute of Uses was repealed. Third, a number of technical rules of no intrinsic value were repealed, such as the Rule in Shelley's Case (1581), 1 Co.Rep. 88b (which treated words which appeared to create interests in remainder in land as merely defining the extent of the prior owner's interest), the rule in *Whitby* v. *Mitchell* (1890), 44 Ch. D. 85 (which prevented a testator from leaving any property to the children or remoter issue of a person then unborn), and the doctrine of interesse termini (that a lease could not be effective until the lessee took possession of the land). Fourth, the technical and complex rules governing legal future interests in land, derived partly from feudal law and partly from the operation of the Statute of Uses, were discarded by making it possible for future interests in land to exist only in equity.

2. Assimilation of the Law of Real Property to that of Personal Property.—The difference in nature between land and chattels makes impossible any close assimilation of the differing legal rules to which they are subject. Nevertheless, some degree of approximation has been achieved. First, both realty and personalty now devolve on the same persons on an intestacy. Formerly, realty passed to the heir, whereas personalty was divided among the next of kin (*see* Personal Property); the new system is in the main a modified version of the former system governing personalty. Second, the grantor's whole interest will now normally pass on a conveyance of land, even if he fails to use words of limitation which were formerly required to pass it. Third, personalty can now be entailed in the same way as realty.

3. Simplification of Conveyancing.—There has been a reduction in the number of legal estates and interests in land which can exist. The only two estates which can exist at law today are a fee simple absolute in possession and a term of years absolute (*see* Landlord and Tenant; Mortgage); thus an entail or life interest is now necessarily equitable. In addition, only five classes of interests in land can now exist at law; the most important are rent charges, easements, and similar rights, if either perpetual or for a term of years absolute. A purchaser without notice of a right takes free from it if it is equitable, but subject to it if it is legal, so that this change effects some reduction of the risk to a purchaser. Second, there has been an extension of the curtain principle, whereby a purchaser of land is concerned only with the legal estate, and the rights of those with equitable interests, which are kept "behind the curtain," are overreached. Third, many more interests in land now require registration as land charges if they are to bind a purchaser. Fourth, the areas in which registration of the title to land is compulsory have been extended (*see* Title to Land). Fifth, no legal estate in land may now be vested in an infant; the land is made alienable by treating it as settled land or subjecting it to a trust for sale, according to whether the infant is entitled solely or jointly with others.

4. Joint Ownership of Land.—Originally four forms of joint ownership of land were recognized by the common law: joint tenancy, tenancy in common, co-parcenary, and tenancy by entireties.

A joint tenancy is created when land is granted to two or more persons with no words indicating that they are to take separate interests. Each of the joint tenants has an equal and identical interest in the whole of the land. On the death of any joint tenant his interest automatically accrues to the survivors. Corporations could not be joint tenants until 1899, when statute altered the common-law rule. The joint tenancy can be severed by one joint tenant disposing of his interest; by agreement; and, since 1925, by notice. This converts it into a tenancy in common.

In a tenancy in common, the owners are entitled to undivided shares which need not be of equal size. On the death of a tenant in common his share does not accrue to the surviving tenants in common, but passes with the rest of his estate.

Co-parcenary was a form of joint ownership which arose when two or more persons became jointly entitled to land by descent. This arose at common law where land passed to two or more females as heirs; or, according to the custom of gavelkind, where it passed to two or more persons. Co-parceners are generally in the same position as tenants in common.

Tenancy by entireties (abolished by statute in 1882) arose when land was conveyed to or devolved upon husband and wife during the coverture in circumstances when otherwise they would have taken as joint tenants. They were together regarded as one person, and each owned the whole. Their interests could not be severed, and when one died the survivor took the whole.

Before 1926, all co-owners could be compelled to partition the land between them: co-parceners by common law; other joint owners, except copyholders, by statutes of Henry VIII; and copyholders by the Copyhold Act, 1841. Actions for partition are no longer appropriate, because the co-owners' beneficial interests are now only interests under a trust. Partitions, however, are still effected by deed where all parties are of full age.

The 1925 legislation provided that the only form of joint ownership that could subsist in a legal estate was a joint tenancy. The joint tenants hold as trustees for sale (*see* below), upon trust for the beneficial joint owners as joint tenants, tenants in common, or (exceptionally) co-parceners, as the case may be, in equity. That tenancy in common and the fast-disappearing co-parcenary can only exist as equitable interests means that a purchaser of a legal estate is not concerned with them. The equitable interests are overridden and take effect against the proceeds of sale. A purchaser has to deal with a maximum of four joint tenants instead of with an unlimited number of tenants in common with varying interests.

Party walls—*i.e.*, walls dividing properties owned by different people—constitute an important example of property in joint ownership. Previous to the legislation of 1925, when built along a boundary they would often be owned by the neighbours as tenants in common. To maintain the principle that tenancy in common could subsist only in equity, and yet to avoid the injustice of applying to party walls the *jus accrescendi* of the joint tenancy, the Law of Property Act, 1925, provided that such walls should be divided vertically, each half being in separate ownership, but with the benefit of and subject to mutual rights of support.

5. Settled Land and Trust for Sale.—The 1925 property legislation made many changes in the law governing settlements of land. During the 19th century, the trust for sale had emerged as

an alternative form of providing for persons in succession. In the case of settled land, control of the land was in the tenant for life; any capital money which arose on any transaction had to be paid to the trustees of the settlement, but it was the tenant for life who had both the day-to-day control of the land and the various statutory and other powers, such as to sell, lease, or otherwise dispose of the land. In the case of a trust for sale, it was the trustees who had the control and the powers, and the main interest of any life tenant was merely to receive the income from the land. This form of settlement, sometimes called a trader's settlement, was appropriate to a row of suburban villas, whereas the rural estates of the nobility and gentry were held as settled land.

The Settled Land Act, 1925, provided that the legal estate in settled land should be vested in the tenant for life as trustee, and required every settlement to be made by two documents, the vesting instrument and the trust instrument. The vesting instrument is a short document containing the few particulars as to the trustees, the tenant for life, the powers, and the land itself, which a purchaser needs to know. The trust instrument in addition sets out all the trusts of the settlement, but it is behind the curtain and does not concern a purchaser. If there is no tenant for life, or the tenant for life is an infant, the statutory owner (usually the trustees of the settlement) takes the place of the tenant for life. The act also repeats and extends the powers conferred by the Settled Land Act, 1882, and makes the machinery of the act apply to virtually all cases where persons are entitled to land in succession, even if no life interest exists, provided the land is not held on trust for sale. When the settlement comes to an end, the trustees should execute a deed of discharge unless there is a document on the title which shows that the land is no longer settled.

No great changes have been made in trusts for sale, save that the trustees now have all the powers of a tenant for life of settled land. A power to postpone sale indefinitely is now implied in all trusts for sale, and many such trusts are created with the intention that the land shall be retained rather than sold.

C. Other 20th-Century Aspects

1. Social Control of Land.—Apart from the many reforms of the substantive law, the predominant feature of the 20th century has been the emergence and statutory recognition of the doctrine, developed piecemeal and never explicitly set forth, that under modern social conditions in an overcrowded country the right of a landowner to do as he wishes with his own must be subordinated to the public interest. Thus many important provisions have been enacted to protect tenants of dwelling houses, business premises, and agricultural land from being evicted when their tenancies expire and from suffering increases of rent. From the landowner's point of view, these provisions fetter his freedom of action. Again, even if the landowner farmed the land himself, until 1958 he was liable to dispossession for failure to attain the required standard of efficiency (*see* Land Tenure: Economic and Agrarian Aspects).

Yet again, under the legislation governing town and country planning, any development of land is subject to stringent control. The Town and Country Planning Act, 1947 (now replaced by an act of 1962), imposed on all land in England and Wales as from July 1, 1948, a comprehensive system of control, unrecognizable by those who drafted the first timid planning statute, the Housing, Town Planning, etc., Act, 1909. Subject to certain exceptions, no development may be carried out without the permission of the local planning authority, usually the County Council; and "development" is widely defined to include any building, engineering, mining, or other operations on land or the making of any material change in the use of land. The act also imposed a liability to pay to the state a development charge in respect of any planning permission granted, representing the increased value of the land due to the permission; but this liability, together with provisions for making some compensation to landowners for this new burden, was repealed as from Nov. 18, 1952, by the Town and Country Planning Act, 1953. Legal opinion was divided about the effect of the act of 1947 on the fee simple to land. Some even urged that a landowner no longer had a fee simple in the land, but only in the existing use in the land; others held that no alteration had taken place in the estate in the land, and that the only change was that the fruits of ownership had become less sweet, which was nothing new in land law. This latter view had the allegiance of the great majority of practitioners, and is almost certainly also correct in theory. (*See* also City Planning.)

2. International Law.—In general, land is governed by the law of the country in which it is situate (*lex loci rei sitae*), and English courts will not adjudicate upon the title to foreign land. Like so many rules of the common law, however, this rule has been qualified by equity. If the proposed defendant to an action is within the jurisdiction, and he is bound by some equitable obligation, equity will assume jurisdiction even though the subject matter of the dispute is foreign land; for equity acts *in personam*. Thus in *Penn* v. *Lord Baltimore* (1750), 1 Ves.Sen. 444, a decree of specific performance was made against a defendant in England in respect of an agreement relating to the boundaries of Pennsylvania and Maryland. Again, where the defendant is within the realm, jurisdiction has been assumed over equitable rights under mortgages of foreign land. But bare questions of the title to foreign land, or damages for trespass to it, are left to the courts within whose jurisdiction the land lies.

D. Conveyancing

Conveyancing is the art or science of creating and transferring interests in property, especially in land. The two main divisions of the subject are investigation of title and drafting. Before a transaction such as a purchase or mortgage can be completed, the purchaser or mortgagee must be satisfied that the vendor or mortgagor is able to convey or mortgage the land, and for this purpose his title must be investigated; *i.e.*, his documents of title must be examined and considered, and any necessary inquiries and searches of registers must be made. Only if this investigation is satisfactory will the necessary conveyance or mortgage be drafted. Leases, settlements, and wills also occupy much of a conveyancer's time. In the work of drafting great reliance is placed on well-tried precedents to be found in the books of model forms which have been collected and published since printing became common.

1. Contract.—The practice in modern English conveyancing may best be illustrated by taking as an example the simple transaction of purchasing a house. After negotiating, the parties usually strike a bargain subject to contract. This morally commits them to the sale and purchase of the house at the agreed price, but neither is legally bound; usually the parties then proceed to the preparation of a formal contract. The vendor's solicitors first prepare and send to the purchaser's solicitors a draft contract, providing for the mode in which the transaction is to be carried through, the title which the vendor will show, and any special provisions such as the imposition of restrictive covenants on the purchaser or the retention of easements by the vendor.

The purchaser's solicitors then send to the vendor's solicitors written inquiries on draft contract, which are mainly concerned with matters such as the existence of rights adverse to the property, whether public (*e.g.*, burdens under town planning legislation) or private (*e.g.*, the rights of tenants under rent restriction legislation). The purchaser's solicitors at this stage search the appropriate land charges registers and other public registers. If the answers to these inquiries and searches are satisfactory and the terms of the contract are agreed, the draft contract is engrossed in two parts, the vendor and purchaser each sign one part, and upon the exchange of these parts the parties are legally bound by the contract.

Where the property is sold by auction, this procedure is somewhat varied. The auction is conducted on the footing of particulars and conditions of sale prepared by the vendor's solicitors. These describe the property to be sold ("particulars") and state the terms upon which it is to be sold ("conditions"); and the purchaser to whom the property is knocked down is required at the conclusion of the auction to sign an agreement to purchase the property upon these terms. The purchaser accordingly has no opportunity for making preliminary inquiries except any that he may be able to make before the auction as a possible prospective purchaser.

Whether the sale is by private treaty or by auction, the contract normally requires the purchaser to pay a deposit, usually amounting to 10% of the purchase price. This may be made payable to an agent for the vendor or to a stakeholder, but in either case it is treated as a token of good faith by the purchaser and will usually be forfeit to the vendor if the purchaser defaults; otherwise, it is treated as an advance payment of part of the purchase money.

2. Abstract of Title.—Once the contract has become binding, the vendor must within the time provided by the contract deliver to the purchaser the abstract of title. This consists in part of an epitome of the various documents whereunder the vendor has become entitled to the property, and partly of a recital of events such as deaths and grants of probate affecting the title to the property. The abstract must start with a good root of title (*e.g.*, a transaction such as a sale or mortgage) and trace the devolution of the property from this root to the vendor. Unless otherwise agreed the root of title must be at least 30 years old.

The purchaser's solicitors then examine the abstract against the various documents upon which it is based, and send to the vendor's solicitors written requisitions on title. These are a series of questions seeking explanation or confirmation on any difficulties or discrepancies which have emerged from considering the abstract. With the simplification of conveyancing effected by the property legislation of 1925 and the modern growth of public and social control of land, requisitions have tended to deal less and less with the title to the land in the conveyancing sense and more and more with the existence of rights and duties adverse to the beneficial enjoyment of the land by the purchaser; it is common for requisitions to repeat most or all of the matters dealt with in the inquiries on draft contract. The vendor must deliver written replies to requisitions on title within the time stated in the contract, and the purchaser is entitled to make further requisitions on any points not satisfactorily dealt with.

3. Conveyance Form.—When the title has been examined and accepted, the purchaser's solicitors prepare a draft conveyance of the property, which is sent to the vendor's solicitors for amendment and approval. The following is a precedent of a very simple conveyance.

THIS CONVEYANCE is made the 1st day of February, 1966, BETWEEN Orlando Gibbons of No. 1 Morley Street, Dowland in the County of Tallis, Clerk (hereinafter called "the Vendor") of the one part and John Bull of No. 1 Weelkes Street Farnaby in the County of Tye, Civil Servant (hereinafter called "the Purchaser") of the other part

WHEREAS—

(1) The Vendor is the estate owner in respect of the fee simple of the property hereby assured for his own use and benefit absolutely free from incumbrances

(2) The Vendor has agreed with the Purchaser to sell to him the said property free from incumbrances for the price of £7000

NOW THIS DEED WITNESSETH that in consideration of the sum of £7000 now paid by the Purchaser to the Vendor (the receipt whereof the Vendor hereby acknowledges) the Vendor As Beneficial Owner hereby conveys to the Purchaser ALL THAT messuage or dwellinghouse with the yard gardens offices and outbuildings thereto belonging known as No. 1 Byrd Street Purcell in the County of Norcome which premises are more particularly delineated and coloured pink on the plan annexed to these presents TO HOLD the same unto the Purchaser in fee simple

IN WITNESS WHEREOF the parties to these presents have hereunto set their hands and seals the day and year first above written.

SIGNED SEALED and DELIVERED by the Vendor in the presence of Edward Elgar, Clerk to Messrs. Delius, Field & MacDowell Solicitors) Orlando Gibbons (Seal)

The constituent parts of this conveyance are as follows: (1) First, there is the commencement ("This Conveyance") and date. (2) Next, there are the parties. Each person or group of persons with a distinctive function is expressed as being parties of a particular "part," with the parties who do the conveying set out first and the parties receiving mentioned last. Thus if the property is settled land subject to a mortgage, the parties would be the vendor of the first part, the trustees of the settled land of the second part, the mortgagees of the third part and the purchaser of the fourth part. (3) The recitals ("Whereas—") explain how the vendor became entitled to the land (narrative recitals) and how and why the existing state of affairs is to be altered; *e.g.*, because there is an agreement to sell (introductory recitals). The modern tendency is to reduce recitals to the minimum, though the old practice of inserting elaborate recitals sometimes proved useful in later years when documents were lost or destroyed or facts had been forgotten. (4) The testatum ("Now this Deed Witnesseth") indicates the beginning of the operative part of the conveyance, while (5) the consideration and (6) the receipt clause record the payment and receipt of the purchase price. The receipt clause makes it unnecessary to have a separate receipt; and a solicitor who produces a deed containing a receipt clause executed by his client is deemed to have his client's authority to receive the money payable. (7) The operative words ("the Vendor As Beneficial Owner hereby conveys") effect the actual conveyance of the property. The words "As Beneficial Owner," however, have an important technical effect, for their use imposes upon the vendor certain covenants for title. In general, it is for the purchaser to satisfy himself before completion that the conveyance will effectually carry out the terms of the contract, and if it does not, he usually cannot after completion rely upon any provision in the contract; the contract is said to be merged in the conveyance. However, the covenants for title give him a limited measure of protection. Four covenants are normally implied: (*a*) that the vendor has power to convey the land, (*b*) that the purchaser shall have quiet enjoyment of the land, (*c*) that the land is free from any incumbrances other than those subject to which it is expressed to be conveyed, and (*d*) that the vendor will execute any further conveyance or other document needed to perfect the purchaser's title. If the property sold is leasehold, there is also implied a covenant that the lease is valid, the rent has been paid, and the covenants in the lease duly performed. These covenants are not absolute warranties, however, for the vendor's liability is normally limited to the acts of himself and of those claiming under him; he is not liable for the acts of any of his predecessors in title except those through whom he claims by an unbroken chain of gifts or marriage settlements. He is thus not liable for the acts of previous vendors, though the benefit of the covenants for title given by them runs with the land and passes to the purchaser. (8) The "parcels" describe the land conveyed, usually by reference to a plan. (9) The habendum ("to hold . . .") shows whether the purchaser takes for his own benefit or upon trust for others, and contains the words of limitation ("in fee simple") which limit, or mark out, the estate which he takes. Before the Conveyancing Act, 1881, the fee simple could normally be conveyed only by using the word "heirs"; *e.g.*, "to A and his heirs." That act introduced "in fee simple" as an alternative, and the Law of Property Act, 1925, s.60, made words of limitation unnecessary by providing that the fee simple was to pass unless a contrary intention was shown. In practice, however, it is usual to employ the words "in fee simple" to avoid doubt. If the property is being conveyed subject to any lease, mortgage, or other incumbrance, or free from some previously existing incumbrance, this is stated in the habendum. And where any special covenants or stipulations are to be entered into, or the vendor is to give the purchaser an acknowledgment of his right to the production of any deeds retained by the vendor, and an undertaking for their safe custody, this follows the habendum. (10) Finally there is the testimonium ("In Witness Whereof . . .") and the attestation clause ("Signed Sealed and Delivered . . ."); these need no explanation.

4. Completion of Transaction.—When the draft conveyance has been agreed, the transaction is ready for completion. The conveyance is engrossed, normally by having a fair copy typed on parchment substitute. This is executed by the vendor and delivered to his solicitor in escrow (*i.e.*, on condition that it is not to be effective unless the transaction is duly completed). If the purchaser is to enter into any covenants or other obligations with the vendor, a further copy will be engrossed and executed by the purchaser in escrow. A completion statement is prepared, apportion-

ing the rates, taxes, and other outgoings up to the day fixed for completion and showing the balance of purchase money payable, and the purchaser obtains a banker's draft for the amount due. Completion normally takes place at the offices of the vendor's solicitors or, if the property is mortgaged, at the office of the mortgagee's solicitors. In return for the banker's draft the conveyance executed by the vendor is delivered to the purchaser's solicitors, with the title deeds relating to the property; the purchaser is then free to take possession of the property. He next has the conveyance stamped under the Stamp Act, 1891; with certain mitigations where the consideration does not exceed £6,000, the normal rate of duty is 1% of the purchase price. The transaction is then complete.

Where the title to land is registered at HM Land Registry (*see* TITLE TO LAND), conveyancing procedure is simplified. The abstract of title and the production of deeds tracing the devolution of title for at least 30 years is replaced by the sending from the vendor to the purchaser of a copy of the current entries on the register. Provided that the vendor is there shown as registered proprietor his title cannot be impugned. Simplified forms of document have been introduced for use in dealings with registered land. The transfer, for instance, which takes the place of the conveyance, omits all recitals, and reduces the description of its title to a reference to its title number. A dealing with registered land is not completed until recorded at HM Land Registry, for which purpose the documents have to be lodged after completion and stamping. In the case of the purchase of a property situated in an area in which registration of title has been made compulsory, but with a title as yet unregistered, the deeds must be lodged for registration at HM Land Registry within two months of completion, or the purchaser will not acquire a legal estate.

5. Leasehold Procedure.—Substantially the same procedure is followed where the property conveyed is leasehold instead of freehold, though the assignment which takes the place of the conveyance is somewhat different in form. Subject to any agreement to the contrary, the vendor need not show title to the freehold out of which the lease was created. Unless otherwise agreed, he must, where the title is not registered, commence his abstract of title with the lease, however old, and trace its devolution for at least 30 years prior to the sale. Where the title is registered, an abstract or copy of the lease together with a copy of the entries on the register suffice. The purchaser must assume, unless the contrary appears, that the lease was duly granted; and on production of the receipt for the last payment due for rent before actual completion, he must assume, unless the contrary appears, that all the provisions of the lease have been observed up to the date of actual completion. The purchaser is subject to an implied covenant to pay the rent and observe and perform the covenants and provisions of the lease and keep the vendor indemnified in these respects. On the other hand, where the transaction consists of the grant of a lease, there is normally no contract and no investigation of title; the parties negotiate the terms of the lease and not until completion is either party legally bound to the other. The same applies to mortgages and settlements, except that sometimes marriage settlements are preceded by marriage articles, which set out in brief form the main provisions of the settlement and make it possible for the drawing up of the formal settlement to be postponed until after the marriage has been solemnized.

6. Conveyancing Counsel to the Court.—These are appointed by the lord chancellor under the Supreme Court of Judicature Act, 1925, s. 217, as amended by the Administration of Justice Act, 1956, s. 14; there may be any number from three to six. They must have practised as conveyancing counsel for at least ten years, and their function is to assist the Chancery Division of the High Court in matters of conveyancing; *e.g.*, in investigating title or settling deeds. Under order 51 of the rules of the Supreme Court, business is referred to them in rotation, and the court may act on the opinion given by conveyancing counsel in any matter referred to him, though any party may require the matter to be referred for decision by the judge at chambers or in court.

(R. E. MY.; T. M. AL.)

II. UNITED STATES LAW

The law of real property of all the U.S. states except Louisiana (whose legal system was based upon the Code Napoléon) was derived principally from the common law of England, and for generations American property lawyers relied upon the standard English texts; *e.g.*, Sir William Blackstone's *Commentaries,* Sir Edward Coke's *Coke Upon Littleton,* William Cruise's *Digest of the Laws of England Respecting Real Property,* and Charles Fearne on *Contingent Remainders.* Even after James Kent's *Commentaries on American Law* and other important U.S. treatises were available, students of property in the U.S. continued to use the English textbooks of the day until those books came to be so cluttered with expositions of the English statutes of the 19th and 20th centuries that they were no longer helpful either as introductions or guides to the U.S. law.

But the U.S. law of real property, even though derived principally from the English law, is not uniform from state to state. Under the constitution of the United States, jurisdiction of land is vested primarily in the states rather than in the federal government. Conditions, both physical and social, vary greatly from state to state and problems relating to land are traditionally deemed to be peculiarly of local rather than national concern. The American Bar Association has sponsored a variety of uniform or model acts, such as the Uniform Acknowledgment Act, designed to achieve uniformity in a few isolated fields, but these have not been generally adopted and there seems to be little sentiment, even among the members of the organized bar, in favour of making the law of real property uniform throughout the country.

1. Tenure.—The colonial charters usually provided that the lands in North America were to be held of the English crown in "free and common socage," the least burdensome of the English forms of tenure. Military and copyhold tenures did not obtain a foothold in America. Indeed, so distasteful to the Americans were the notions of feudalism that the attempt to collect the rents and enforce the other obligations which were incidents of socage tenure either caused or contributed to serious incidents such as Bacon's Rebellion in Virginia in 1676 and the antirent disturbances in New York in the early years of the 19th century. Following the American Revolution, feudal tenure was either abolished by statute or, if not formally abolished, became for most purposes obsolete.

Although tenure early ceased to be an important institution of the American land law, many of the archaic rules of law which had been developed in England to further feudal policies were adopted in America and continued for many years to be vital elements of the American law of property. The history of the U.S. law consists, very largely, of the substitution of modern rules for the ancient feudal rules which should have been, but were not, abolished when feudalism became obsolete. In 1936 the American Law Institute reported in the *Restatement of the Law of Property* that the rule of law which required that a deed include the ancient formula of words of inheritance (*i.e.*, "and to his heirs") in order to transfer an interest larger than a life estate, and the equally technical rule, known as the Rule in Shelley's Case —which, when controlling, caused an estate of inheritance to be vested in a transferee who was intended to acquire only a life estate—were still a part of the U.S. common law. Fortunately, most of the states had abolished these rules and others like them before 1936, though in a few jurisdictions they had survived. In Illinois, for example, the Rule in Shelley's Case was not abolished until 1953, though it had been repealed in England by the property legislation of 1925.

2. Estates.—The English scheme of estates in land was adopted with but few changes although that system, even at the time when it was transplanted in America, included many relics of feudalism which had no relationship to conditions in America. The English classification of estates as freehold and nonfreehold was adopted with the result that leasehold interests in land (*e.g.*, a term for 99 years) were considered personal property, designated by the term "chattels real" and treated for many purposes as chattels rather than land. The term "real property" was reserved, as it had been in England, for the freehold interests in land. These included the

fee simple, the fee tail, and the life estate.

Fee Simple.—The fee simple was the largest estate which could be created. Subject only to the general limitations which were imposed upon owners of property, the owner of an estate in fee simple absolute might use the land as he wished. The estate was freely transferrable and, unless conveyed or otherwise encumbered, it passed upon the death of the owner either to the beneficiary designated by the owner in his will or, in the absence of a valid gift by will, by operation of law to the owner's heirs at law. Primogeniture, though it had been recognized in some sections of America in the colonial period, was not deemed to be consistent with American ideals, and it, together with the preference of males over females, was abolished for most purposes during the period of the Revolution.

Fee Tail.—The fee tail was introduced into some or perhaps most of the American colonies at an early date and brought with it the distinguishing features that it had in England including the elaborate paraphernalia of fines and common recoveries by which the owner of such an estate might, if he wished, bar the entail and convert his estate tail into an estate fee simple. In most of the states, entails were abolished by statutes which provided either that the donee who was intended to have an estate tail should have an estate in fee simple or that the donee should acquire a life estate and that the issue of the donee should take an estate in fee simple.

By 1936 the estate tail was recognized in only half a dozen states and a simple disentailing deed had long since been substituted for the fine and the common recovery as a means of converting the estate tail into an estate in fee simple. In Iowa, Nebraska, Oregon, and South Carolina the courts had held that a conveyance to one and his bodily heirs created a fee simple conditional, the ancient common-law estate which had been abolished in England by the enactment of the statute *De Donis Conditionalibus* in 1285. In Nebraska the fee simple conditional was abolished in 1941 when the state enacted the Uniform Property Act which substituted an ordinary fee simple for the fee simple conditional.

Life Estate.—The smallest of the freehold estates was the life estate, an estate the duration of which, as the name indicates, was limited to the lifetime of a natural person. The measuring life might be either that of the owner of the estate or the life of another person than the owner, in which case it was known as an estate pur autre vie. Life estates might be created either by a conveyance which was executed for the purpose of creating such an estate or by operation of law as were the estates of dower and curtesy which were common-law incidents of a marriage relationship and entitled the surviving spouse, under certain circumstances, to life estates in some or all of the real estate which the deceased had owned at any time during the marriage.

3. Future Interests.—The complicated and largely archaic English system of future interests was adopted in colonial America with only a few alterations. The reforms which had been effected by the enactment of the Statute of Uses, 1535, were, of course, incorporated into the American law, but with few other exceptions the ancient common-law rules which had been developed to meet the needs of feudal England governed the creation of future interests in America. This branch of the law of property became, in America as it was in England, notorious for distinctions which were so technical and refined that they were difficult even for the most experienced conveyancers to apply. Consequently, the attempt to create any future interests except the simplest types would often occasion great uncertainty concerning title and serve not only to impede the development of the land out of which they had been created but also to defeat the wishes of the transferor.

The Revised Statutes of New York, 1827, abolished many of the feudal rules which encumbered this branch of the law of property. Unfortunately, the attempts of the commissioners who drafted the New York revision of 1827 to reform the law of future interests were not so successful as they should have been because they attempted to improve the relatively modern rule, known as the Rule against Perpetuities, which the English judges had developed to control the creation of the modern types of future interests which had been introduced into the law of England by the enactment of the Statute of Uses. The English Rule against Perpetuities was far from perfect, but the statutory substitute which the New York commissioners devised created more problems than it solved. Nevertheless, the New York statutes of 1827 and the Field Civil Code, which New York rejected in the mid-19th century, were copied by a number of the states, especially those in the West. But reform in the law of future interests, as in the law of real property generally, was slow, for courts and legislatures were reluctant to abandon the ancient rules.

Fortunately, future interests were not commonly created and, though now and then complicated settlements were executed, they did not become customary as they were in England, where title to much of the land in the realm was fettered by marriage settlements, a form of transfer which had been devised by the English conveyancers as a means of keeping land within the family. Thus, even though the English law of future interests was outmoded when it was received in North America, it did not seriously stifle the development of the country because, at any one time, only a very few tracts were burdened by future interests.

Though the marriage settlement was seldom used in America to keep land within a family, the various gift, estate, inheritance, and income taxes of the 20th century afforded a strong incentive to owners of substantial amounts of property to resort to various types of settlements as a means of protecting the family, not from an irresponsible member, but rather from the tax collectors. The will of Pres. Calvin Coolidge by which he left all his property to his widow was a model of brevity and simplicity, but, as conveyancers noted, even a simple form of family settlement would have reduced substantially the estate and inheritance tax liability of the Coolidge family. The will of Sen. Robert A. Taft, executed a quarter of a century later, established a fairly elaborate family settlement; but it was drafted with such skill that the liability of the Taft family for estate and inheritance taxes was very much less than it would have been had the Coolidge will been used as a model.

4. Transfer of Title.—*Conveyances.*—By the time the American colonies were established, deeds had in England very largely supplanted the ancient feudal formalities for conveying real property. In America, the rule that title to land might be transferred by the execution of a deed was established at an early date. The form of the deed which was used might be one which had been developed by the English conveyancers or it might be one which was prescribed by an American statute. It might be either a warranty deed, which included covenants for title by which the grantor undertook to protect the grantee and his successors against defects in the title, or a quitclaim deed which was used to transfer the grantor's interest, if any, without any warranty as to title. Such deeds, whether warranty or quitclaim, operated either as a modern counterpart of a common-law conveyance by livery of seisin or as a conveyance to uses which was within the operation of the Statute of Uses. The statutes usually required that the deed, if it was to be effective for all purposes, should be signed by the grantor, witnessed and acknowledged before a notary public or other public official.

Recording Acts.—Secret conveyances, though they were usually valid as between the parties, were not enforceable against bona fide purchasers for value without notice because recording systems had been established by legislation in all of the American states. The investigation of title to lands in the U.S. was greatly simplified, not only because the records of conveyances were available for inspection by the public but also because a large portion of the land within the United States had been surveyed by the federal government under a uniform, rectangular system which was established by an act of Congress of 1796 as a part of the program to transfer the lands of the United States from public to private ownership.

Abstracts of Title.—As the years passed the public records became more and more voluminous and cumbersome. To facilitate land transfers it became customary in many localities to rely, for evidence of ownership, upon abstracts of title which summarized in convenient form the public records of the deeds and other

instruments which affected the title to the particular tract which was being transferred. The abstracts of title were made either by lawyers or perhaps more frequently by specialists who were not members of the bar.

Title Insurance.—Toward the end of the 19th century the practice developed for the large title companies, which dominated the business of searching the public records in the larger urban areas, to issue insurance policies to indemnify purchasers against loss occasioned by defects in title which the examination of the title had not revealed but which were, nevertheless, enforceable against purchasers. Title guarantee policies are now commonly used in the closing of transactions relating to land.

Torrens Titles.—The determination of title to land either by the examination of the public records, or by the examination of an abstract of title, or by the procurement of a policy of title insurance was often either slow, or expensive, or both. In an effort to avoid these difficulties, about 20 states adopted the Torrens Acts, which permitted the substitution of registration of title and the issuance by public officials of certificates of title for the recording of deeds and other transactions which affected title to land; the system, however, failed to make headway. (*See* TITLE TO LAND.)

Mortgages.—Mortgages in the United States took the form either of a transfer of title to the creditor or to a trustee for the creditor subject to a provision that the transfer would be nullified if the debtor should pay the debt as he had undertaken to do. As in England, the form of the deed concealed the fact that the effect of the transaction had been revolutionized by the development by courts of equity of a right to redeem, known as the equity of redemption, which enabled the mortgagor to recover his property even though he had failed to pay the obligation at the time specified in the mortgage or trust deed. A number of states, following the lead of New York, established the rule that, whatever the form of the deed which had been executed, the mortgagor continued to own the land subject only to a lien which, though it provided a basis for a decree of foreclosure should the mortgagor default, did not entitle the mortgagee, qua mortgagee, to have possession of the land. In many jurisdictions, the decree of foreclosure directed that the land should be sold by an officer of court to the highest bidder and that the proceeds, if any, which remained after the mortgage debt and the expenses of the foreclosure had been satisfied should be paid to the mortgagor. Frequently, the mortgagor's equity to redeem the property even after he had defaulted was supplemented by a statutory right of redemption which entitled the mortgagor, if he wished, to retain the property free from the lien of the mortgage by paying, not the amount of the debt, but rather the price which had been obtained at the judicial sale.

During the depression of the 1930s, moratoria statutes were enacted in many states to shield mortgagors from the hardships occasioned by the collapse of the economy. Some extended the time within which mortgagors might redeem the security. Others protected them from personal liability upon the debts which were secured by mortgages. Under the Frazier-Lemke amendment to the Bankruptcy Act, 1935, farmers were given the opportunity to retain possession of their farms pending an arrangement in bankruptcy and permitted to wipe out the mortgage by paying, not the amount due on the debt, or the price obtained at a foreclosure sale, but, instead, the value of the property as determined by appraisers under the supervision of the bankruptcy court. (*See* also MORTGAGE; BANKRUPTCY.)

5. Rights of Enjoyment.—In the United States, as in England, the rules of law which governed the use and development of land were based upon the assumption that the owner should have the fullest possible freedom to use the land as he wished. As an owner, he was entitled to use the land as he chose without obtaining either consents from his neighbours or licences from the state. He might let the land remain unused, or, if he preferred, he might alter or destroy its substance.

Tracts of lands are not, however, independent. The development of one tract, especially if it is small, may often affect the enjoyment of other tracts. If, therefore, owners were to be secure in the privilege of using their land, the power of each must be restrained to the extent that was necessary to ensure that each would have the maximum freedom which might be attained in a civilized society. It was therefore established that, although an owner of land might leave it in its natural state even though this occasioned harm to others, he was not privileged to harm others either by using it in a careless or negligent manner, or, as it became clear in the 20th century, by using it in an ultrahazardous way even if he did so with the greatest possible care.

Nor would ownership of land justify an encroachment, even though innocent, upon the land of another, whether the encroachment was on the surface, underground, or in the air. This limitation did not mean, as some once thought, that all flight over land without the consent of the owner was unlawful. It meant, instead, that such flight at low altitudes was unlawful even though the upper boundary of the air space which must not be invaded could not be fixed as precisely as boundaries upon the surface could be marked out by a surveyor.

Moreover, the owner of land might be held accountable even though he had kept within his boundaries and his use had been neither negligent nor ultrahazardous. He was required, in addition, to refrain from any use, however carefully it might be conducted, which interfered unreasonably with the enjoyment of neighbouring lands. The difficulty inherent in this limitation upon the freedom of the owner was that it was so general that it was vague and hence extremely difficult to apply.

In some situations, the standards of reasonableness were definite. An obstruction of a vista or of the access of light and air to an adjoining tract by building close to the boundary was held not to be an unreasonable use. Some courts, apparently misled by the colourful language of Blackstone's *Commentaries,* announced that even a "spite fence," which had been built only to annoy a neighbour, was not actionable if it had been carefully constructed and did not extend beyond the boundary. This rule had been generally repudiated by the 20th century, although the Supreme Court of Pennsylvania applied it in a case decided in 1947.

On the other hand, an excavation or mining operation which, by disturbing the lateral or subjacent support, caused the soil of neighbouring land to subside was usually deemed to be unreasonable and hence actionable even though the work had been done very skilfully.

In most instances, however, the limitations imposed upon the owners of land with respect to the use and development of their tracts were extremely vague. The test of legality was the reasonableness of the particular use. The standard was that of "give and take, live and let live," and its application required the difficult adjustment of the correlative and interdependent interests of competing owners. Among the factors which were to be considered was the character of the neighbourhood. A use which might be appropriate in one locality might be unreasonable and hence unlawful in another. The application of the common-law rules thus tended to segregate uses and to impose upon landowners a crude system of zoning.

Waste.—The freedom of an owner to use his land might also be limited because his interest was not a fee simple absolute. The owner of a life estate, for example, was ordinarily accountable for waste and was not entitled to use the land in a way which would unreasonably interfere with its enjoyment by the owner who would be entitled to have possession when the life estate ended.

Easements and Restrictive Covenants.—The owner's privilege of use would also be curtailed if his estate, although a fee simple, was encumbered by a property right which entitled another person either to use the land for a limited purpose (*e.g.,* a right of way) or to require that the owner refrain from using the land in a particular way (*e.g.,* a right of access of light to a window).

Originally these restrictions were confined within narrow limits, but in the second half of the 19th century the courts decided that many types of agreements concerning the use of land should bind not only the parties to the agreement but also successors in title except bona fide purchasers who took without notice of the restriction. In the 20th century covenants were often relied upon

in the development of land for residential use to assure prospective purchasers that a wide variety of uses which were thought to be undesirable would be barred from the district. Sometimes covenants were used in an attempt to keep members of a particular race from moving into an area, but enforcement of these was declared unconstitutional by the Supreme Court in the cases of *Shelley* v. *Kraemer* (1948) and *Barrows* v. *Jackson* (1953). (*See* COVENANT: *In Law.*)

6. Social Control of Land.—The freedom of an owner to use and develop his land may also be limited by the necessity of submitting to its regulation or appropriation for the public good. Under the U.S. system the powers of government agencies are restricted by the provisions of the state and federal constitutions; but subject to those limitations, private property in land is subordinated to the interests of the state.

Eminent Domain.—The owner's enjoyment of land is subject to the power of eminent domain, and his land, or an interest in it, may be taken from him so that it may be used for a project which he does not approve. The appropriation must be authorized by a statute which satisfies the various requirements of a valid act including, first, that the appropriation was for a public use and, second, that the owner was paid a just compensation for the interest which was taken from him. (*See* further EMINENT DOMAIN.)

Police Regulations.—The owner of land is also required to submit to police regulations. Even though the loss which the regulation caused an owner was large, he is not entitled, as of right, to be compensated for the sacrifice made for the benefit of the public. Thus in *Miller* v. *Schoene* (1928), 276 U.S. 272, the Supreme Court held that the Virginia landowner who was required to destroy his cedar trees to protect apple orchards in the vicinity from rust was not entitled to be reimbursed either for the value of the trees or for the depreciation in the value of his land.

In the earlier period the typical police regulations affecting the use of land were building codes and other regulations intended to protect the health and safety of those who lived in cities. At one time it was doubtful whether such regulations might be applied to existing structures, but that doubt was resolved in favour of the power by the decision of the New York Court of Appeals in the Trinity Church case (1895).

Zoning.—In the 20th century the scope of regulations imposed upon owners of land was vastly extended. In the case of *Village of Euclid* v. *Ambler Realty Co.* (1926) the Supreme Court upheld the power of the states to classify communities into zones and to impose different regulations as to use within the various zones. Planning commissions were established to formulate programs for community development, and their policies were put into effect by enactment of comprehensive zoning and subdivision ordinances regulating many aspects of the use of land in metropolitan areas.

In most instances, the courts have insisted that these regulations be justified by a showing that they are reasonably related to the protection of the health, safety, and morals of the public, and not infrequently regulations have been held to be unenforceable in particular situations because the requisite showing was not made. Frequently, regulations have been justified on the ground that they had an important relationship to the maintenance by the community of the various public services such as streets, schools, and fire protection, and sewage disposal systems. (*See* also ZONING.)

Efforts to justify land use restrictions upon purely aesthetic grounds have generally been rejected by the courts, but the fact that enforcement of such regulations would enhance the attractiveness of the locality has often been noted by judges in upholding the restrictions.

The power of the state to conserve natural resources by police regulations is widely recognized, and many statutes have been enacted to outlaw land uses that were wasteful in either the physical or the economic sense. The best examples of such legislation are the prorating and marketing schemes which were adopted in the oil-producing states during the depression of the 1930s to protect the petroleum industry from the difficulties created by the collapse of the economy.

RÉAUMUR, RENÉ ANTOINE FERCHAULT DE (1683–1757), French physicist and naturalist who devised the Réaumur thermometric scale, was born on Feb. 28, 1683, at La Rochelle. In 1710 he was charged with the official description of the useful arts and manufactures of France, which led him to many practical researches. He examined and reported on the auriferous rivers, the turquoise mines, the forests and the fossil beds of France; devised a method of tinning iron and investigated the chemical composition of Chinese porcelain and the chemical differences between iron and steel.

Réaumur's thermometric scale (1730) was constructed on the principle of taking the freezing point of water as 0°, and graduating the tube of the thermometer into degrees each of which was one-thousandth of the volume contained by the bulb and tube up to the zero mark. It was an accident dependent on the coefficient of expansion of the particular quality of alcohol employed which made the boiling point of water 80° R.; and mercurial thermometers the stems of which are graduated into 80 equal parts between the freezing and boiling points of water are Réaumur thermometers in name only. Réaumur wrote widely on natural history (*see* ENTOMOLOGY: *History of Entomology*), his best-known work on this subject being the *Mémoires pour servir à l'histoire des insectes*, six volumes (1734–42). He died at La Bermondière, in the old French province of Maine, on Oct. 18, 1757.

REBATE. In the commercial world a rebate is a retroactive refund or credit to a buyer after he has paid the full list price for a product or for a service such as transportation. It contrasts with a discount, which is usually subtracted from the list price before the original payment. Rebating was a popular pricing weapon during the 19th century and was often used by oligopolists to preserve or extend their power over customers. Important customers were granted refunds in secret so that less influential buyers would know nothing of them. Rebating was used so universally by American and European railroad firms that published tariffs were applied only to shippers who were unsophisticated enough to pay them without bargaining for a refund. In U.S. history the rebates received by the Standard Oil Company were major factors in the company's attainment of a monopolistic position in the oil industry.

The motive for rebating among railroad firms lay in their chronically underutilized capacity. Secret rebates seemed a small price to pay for the capture of large freight orders, even though it resulted in unfair discrimination among shippers. The Interstate Commerce Act of 1887 implicitly prohibited rebates by U.S. railroads but the practice continued because of difficulties in detecting it. The growing business monopolies of the era intensified pressure for increasingly large rebates. Big firms coerced the railroads into violating the law and risking prosecution. The railroads, out of desperation, sponsored the Elkins Act of 1903, which put an end to the practice by declaring that a shipper who accepted a rebate was guilty along with the carrier who made the payment.

Rebates are not all vicious and destructive. Some are justifiable incentives that stimulate desirable action on the part of customers. Real estate firms in Europe, for example, gave rebates to buyers to encourage land improvements that would increase the value of adjoining unsold land. A partial refund of interest on a loan for

repayment before the due date was once widely and correctly called a rebate but it is now popularly termed a discount. More dubious is the case of salesmen who offer secret rebates of part of their commission to customers with high sales resistance. As neither employers nor other customers are likely to discover the practice, its prevalence is unknown.

So-called deferred or exclusive patronage rebates are popular for large vendors of perishables, certain services, and consumer durable goods. To receive such a rebate the purchaser must agree to buy certain goods or services exclusively from a particular vendor for a fixed period, usually ranging from 6 to 12 months. In return for this exclusive patronage the vendor refunds a predetermined percentage of the customer's total payments. Deferred rebates can be justified on economic grounds if they are open to all customers and if production costs decline because of the stabilized sales volume of the manufacturer.

Groups of steamship lines (known as conferences) make extensive use of deferred rebates, although they were outlawed for carriage of U.S. imports and exports by the Shipping Act of 1916. The United States restricts rebating more than other industrialized nations because of its uncommonly potent antitrust statutes. *See* also SHIPPING: *Ship Operation.* (Jo. Hy.)

REBEC, a bowed stringed instrument of Middle Eastern origin, was in general use in Europe during the Middle Ages and early Renaissance, and is still commonly used in the folk music of the Balkans. The medieval rebec (the name is derived from the Arabic *rabab*) had a violin-type bridge and tailpiece, and a vaulted back like the lute, either carved from a solid block of wood or constructed from separate ribs glued together over a mold. The European instrument differed from the *rabab* in that the table or soundboard was of wood, rather than of skin. It had no soundpost, and the gut strings, two or three in number, were generally tuned in fifths. Although in western Europe a fingerboard was added at an early date, the Oriental method of "stopping" the strings with the sides of the fingernails of the left hand persisted in some countries until modern times. The medieval rebec was often held against the chest or under the chin; but when the player was sitting the instrument was sometimes held in the Oriental manner, the bottom of the instrument resting on the player's left thigh.

The medieval rebec appears to have been a treble instrument, but by the late 15th century rebecs were being made in several sizes, from treble to bass. The family of rebecs was superseded by the viols by about the middle of the 16th century; the treble rebec, however, survived in western Europe to the 18th century as an instrument for rustic music-making and, in a miniature form, as the dancing master's *pochette.* In modern times the rebec in various forms and tunings is found in the folk music of Greece, Bulgaria, and Yugoslavia, as well as in its original form in the art music of the Middle East. (M. Mw.)

REBECCA RIOTS, the name given to disturbances which occurred briefly in 1839 and with greater violence from 1842 to 1844 in southwest Wales. The rioting was directed against the charges at the tollgates on the public roads, but the attacks were symbols of a much wider disaffection, caused by agrarian distress, increased tithe charges, and the Poor Law Amendment Act of 1834. The rioters took as their motto the words in Gen. 24:60 "And they blessed Rebekah, and said to her, '. . . may your descendants possess the gate of those who hate them!' " Many of the rioters were disguised as women and were on horseback; each band was under a leader called "Rebecca," the followers being known as "her daughters." They destroyed not only the gates but also the tollhouses, the work being carried out suddenly and at night, usually without violence to the tollkeepers. Emboldened by success, the Rebeccaites in 1843 turned their attention to other grievances. The government dispatched soldiers and police to South Wales, and the disorder was quelled. An act of 1844, known as Lord Cawdor's Act, amended the turnpike trust laws in South Wales and lessened the burden of the tollgate system.

See D. Williams, *The Rebecca Riots* (1955). (R. T. J.)

REBELLION, armed resistance for political purposes by nationals of a state against the government, usually resulting in insurrection, civil war, or revolution. In law, rebellion is the act of one who engages in such resistance and is therefore subject to prosecution for treason, sedition, or rebellion. In British history, for example, supporters of the Old Pretender in 1715 and of the Young Pretender in 1745 were punished as rebels. In the U.S. Civil War the federal government regarded the Confederates as rebels although they had been recognized as belligerents by neutral states. A general amnesty after the war terminated prosecution against the leaders. In the South African war of 1899–1902 the Supreme Court of the Cape of Good Hope held that those who joined the burgher forces were liable for treason, although the burghers had been recognized as belligerents (Rex *v.* Louw, 21 C.G.H. Supreme Court Rep. 36, 1905). (*See* TREASON AND SEDITION.)

For historic rebellions *see* titles of specific rebellions. For the status of rebellion in international law *see* BELLIGERENCY. For the usual justifications for rebellion, *see* DEMOCRACY; HUMAN RIGHTS; IMPERIALISM; NATIONALISM; SELF-DETERMINATION. (Q. W.).

REBUS. A simple rebus is the representation of a word or part of a word by a picture of a thing with a similar name. Several may be combined—in a single device, or successively—to make a phrase or sentence. Literary rebuses use letters, numbers, musical notes, or specially placed words to make sentences. Complex rebuses combine pictures and letters. As a means of communication, rebuses may convey direct meanings, especially to inform or instruct illiterate people; or they may deliberately conceal meanings to inform only the initiated or to puzzle and amuse.

An early form of rebus occurs in semiprimitive picture writings, where abstract words, difficult to portray, were represented by borrowing pictures of objects pronounced the same way. These are common in Egyptian hieroglyphs and early Chinese pictographs. Rebus pictures were used to convey names of towns on Greek and Roman coins, or names of families in medieval heraldry (in the so-called canting arms; *see* HERALDRY), and they have often been used for instructional symbols in religious art and architecture. In the Far East, especially in China and Korea, rebus symbols were commonly employed to carry auspicious wishes. Rebus-making was long considered a specialty of Picardy, in France.

Elsewhere in Europe literary rebuses often appeared on family mottoes, personal seals, ciphers, and bookplates and ultimately in games or riddles. A familiar English rebus is the debtor's I O U, for "I owe you."

Popular in the United States after the mid-19th century were rebus picture puzzles in which the indicated addition or subtraction of letters in illustrated words produced another word or a name. Hundreds of these were devised by the puzzlemaking genius Sam Loyd. Such picture riddles have been widely used in U.S. advertising, and, beginning in the 1930s, sequences of them were presented in newspaper contests designed to attract readers. Huge prizes were offered but the final problems were so difficult that only groups of experts could solve them.

RECALL, a device, principally used in the United States, by which voters may remove a public official from office before the expiration of his regular term. Recall is based upon the principle that officials are mere agents of the popular will and as such should be constantly subject to its control (*See* REPRESENTATION). Under the plan, if a specified percentage of the electorate are dissatisfied with an official's conduct and sign a petition for his removal, the officer must face a general election to determine the majority opinion.

Though the general principle of the recall is simple, there are many variations in its practical application. Under some plans the question of removal may be decided in one election, and the question of a successor in a subsequent election, but for economy's sake the two are often combined in one election. The vote required to remove an official is usually a simple majority of those voting. The percentage of signatures required to force an election ranges widely, the average being about 25% of those who participated in

the last general election in that electoral district. An officer elected at a recall election serves out the unexpired portion of the term of the office.

The recall is, in fact, infrequently resorted to and then almost entirely for local officers. The recall found statewide application in North Dakota in 1921 when the governor, attorney general, and commissioner of agriculture were removed. At mid-20th century only a few instances of its being applied to judges were on record, all of them in minor courts. In its statewide application it becomes too cumbersome to be resorted to frequently.

Recall originated in Switzerland where it was made applicable not only to individuals but to the entire legislature. It was suggested in the U.S. Articles of Confederation and discussed in the Constitutional Convention of 1787, but its first practical application in the U.S. was in 1903 in the Los Angeles, Calif., city charter. It was soon adopted by many cities with the commission form of government as the most effective way to control the commissioners in whose hands large powers were placed. It was subsequently adopted in the following states: Oregon (1908), California (1911), Arizona, Idaho, Washington, Colorado, and Nevada (1912), Michigan (1913), Louisiana and Kansas (1914), North Dakota (1920), and Wisconsin (1926). Most of these states had many elective officers not subject to removal by the governor who were, in effect, beyond administrative control during their terms of office.

The term was also applied in the early 20th century to various proposed restraints on the judiciary. Under the slogan "recall of judicial decisions," the Progressive Party under the leadership of former Pres. Theodore Roosevelt in 1912 advocated that "when an act, passed under the police power of the State, is held unconstitutional under the State Constitution, by the courts, the people . . . shall have an opportunity to vote on the question whether they desire the Act to become law, notwithstanding such decision." The 1912 proposal was not adopted, and in some states (Idaho, Louisiana, Michigan, and Washington) the recall was not made applicable to judges on the ground that the judiciary should be independent of popular passions and political pressures.

A general increase in the size of electorates, plus a greater demonstration of responsibility on the part of executives and legislative bodies alike in the second half of the 20th century, tended to diminish use of the recall. Its effectiveness is perhaps not to be measured by its use, but by the restraining influence it may exercise.

(W. W. CR.)

RÉCAMIER, JEANNE FRANÇOISE JULIE ADÉLAÏDE (née BERNARD) (1777–1849), Frenchwoman famous for her charm and conversation in early 19th-century literary and political circles, was born on Dec. 4, 1777, at Lyons. She was married at 15 to the rich banker Jacques Récamier (d. 1830), who was old enough to be her father. From the early days of the Consulate to almost the end of the July Monarchy her *salon* in Paris was one of the chief resorts of fashionable literary and political society. Its habitués included many former Royalists and others, such as Bernadotte (later Charles XIV of Sweden and Norway) and Gen. Jean Moreau, more or less set against the government. She was eventually exiled from Paris by Napoleon's orders. After a short stay at Lyons, she went to Rome in 1813, and later to Naples, where she was on friendly terms with Marshal Murat, then king of Naples, and his wife. Her husband had sustained heavy losses in 1805, and in her later days she lost most of the rest of her fortune; but she continued to receive visitors at the Abbaye-aux-Bois, the old Paris convent in which she took a separate suite in 1819.

Chateaubriand (*q.v.*) was a constant visitor, and, as well as continuing his liaison with her, became the centre of her *salon,* at which he read extracts from his works. Even in old age, ill health, and reduced circumstances Mme Récamier never lost her attraction. She was always renowned for her beauty, and there are well-known portraits of her by J. L. David and François Gérard. Among her admirers were Mathieu de Montmorency, Lucien Bonaparte, Prince Augustus of Prussia, Pierre Ballanche, J. J. Ampère, and Benjamin Constant, but none obtained so great an influence over her as Chateaubriand, though she suffered from his imperious temper. If she had any genuine affection, it seems to have been for Prosper de Barante, whom she met at Coppet, Mme de Staël's country house in Switzerland, which she often visited. She died in Paris on May 11, 1849.

RECEIVER, in English and U.S. law, a person appointed by a court to collect and conserve assets and income, making disbursements only as authorized by the court. He may or may not be entrusted with the active carrying on of a business. Receivers were traditionally appointed by courts of chancery in Great Britain. The Judicature act of 1873, however, conferred power to appoint receivers upon all divisions of the high court. In the United States receivers may be appointed by any court of general equity jurisdiction. State statutes have contributed to the development of the law of receiverships in various types of cases.

In theory a receivership is properly only incidental to the realization of another primary objective and is not recognized as an independent object of litigation. A receiver may be appropriate whenever the court finds a need to conserve property or to distribute funds in litigation. The receiver is deemed an "arm of the court," and the property which he takes into possession is said to come into the custody of the court. Unlike a trustee in bankruptcy in the U.S., he is not deemed to take "legal title."

Typically receivers are appointed on special or general creditors' bills. A court of equity, discharging a long recognized duty to furnish an effective remedy when the remedy at law is inadequate, will entertain a special creditor's bill to reach intangible or concealed property beyond the reach of execution or other legal process and to apply the proceeds to the complainant's claim. A general creditors' bill is particularly appropriate when a creditor can show the need for appointing a receiver to avert the liquidation of a going business enterprise with threatened loss to all concerned. An ensuing general equity receivership may lead to the reorganization of a business association. The receiver may be authorized to conduct the business during the litigation in hopes of effectuating a sale of the business as a going concern. The purchaser may be a business association, frequently a new corporation in which creditors and sometimes former proprietors have interests represented by new securities distributed under a plan of reorganization which has been negotiated by the parties and approved by the court. In the last third of the 19th century, a procedure for reorganizing insolvent railroad corporations was developed in the United States, substantially without statutory authorization, under the description of the "federal equity consent receivership." Certain United States district judges became expert in resuscitating insolvent railroad corporations. A few unsecured creditors of a failing railroad, citizens of some state or states other than that in which the railroad was incorporated, would file a general creditors' bill, showing the need of conserving the liquid assets of the road. A federal court would then have jurisdiction of the proceeding by reason of diversity of citizenship of the parties. Collusive proceedings were entertained in order to keep the railroad running under the protection of a federal court. A plan of reorganization could be negotiated, approved by the court and consummated through judicial sale, typically by the issuance of securities of a new corporation with a revised capital

structure. The equity receivership practice was elaborated and partly codified and reformed by sec. 77, added in 1933 to the U.S. Bankruptcy act of 1898. Initial experience with this statute led to substantial amendments in 1935. The court administers the property through an official called a trustee, but he has the powers of an equity receiver, as well as "legal title" as a statutory successor to the debtor, a concept developed with reference to trustees in strict bankruptcy.

Industrial and mercantile corporations may be reorganized under Chapter X of the Bankruptcy act. Statutory provisions for the intervention of the plans of reorganization make Chapter X proceedings elaborate and expensive affairs, transcending but still largely founded upon equity receivership practice.

In strict bankruptcy in the U.S., the receiver is merely a temporary conservator appointed when needed to serve until the trustee to liquidate the property can be elected by creditors. In England, however, permanent officials designated receivers administer bankrupt estates, but they proceed more in the tradition of bankruptcy liquidation than that of receivers in chancery. The official receiver may take charge of the affairs of a company in compulsory winding up proceedings. Creditors or stockholders may, however, nominate liquidators other than the official receiver.

(J. A. MacL.)

In English law there is a clear distinction between a receiver appointed under an instrument (such as a debenture) and a receiver appointed by order of a court. The powers of a receiver appointed under an instrument depend upon the terms of that instrument and upon the general law of agency. Receivers appointed by a court are generally appointed under section 45 of the Judicature act, 1925. A court has power to appoint a receiver whenever this appears just and convenient, and the typical reason for such appointment is the protection of property for the benefit of interested persons as, for example, pending the trial of an action. Although all divisions of the high court, besides the court of appeal, have power to appoint a receiver, the chancery division most frequently does so. An appointment is as a rule only made in the queen's bench division by way of equitable execution. Applications should be made in the probate, divorce and admiralty division when, for example, proceedings are pending to determine who shall administer a deceased person's estate, or when a wife entitled to alimony needs a receiver of her husband's interest under a settlement. Normally the court can only appoint a receiver when litigation is in process.

In English practice a named person is often made receiver on the motion for an appointment, but if there is any difficulty or dispute the matter is referred to chambers. The court or the court of appeal will not interfere with the master's discretion in appointing unless he makes a mistake in principle. *See* also BANKRUPTCY.

(W. T. Ws.)

RECHABITES, a sort of religious order among the Israelites, analogous to the Nazirites (*q.v.*), with whom they shared the rule of abstinence from wine. They eschewed settled life and lived in tents, refusing to sow grain or to plant vineyards. The Rechabites represented a protest against the contemporary civilization and a reaction toward simplicity of life. Their "father," or founder, was that Jehonadab (or Jonadab), son of Rechab, who encouraged Jehu to abolish the worship of the Tyrian Baal (II Kings 10:15–27).

The "house of Rechab" fled for protection into Jerusalem at the approach of Nebuchadrezzar (Jer. 35), and Jeremiah promised them, as a reward of their adherence to the ordinance of Jehonadab, that they should never lack a man to represent them (as a priest) before Yahweh. Later Jewish tradition states that the Rechabites intermarried with the Levites.

See M. H. Pope, "Rechâb," in *The Interpreter's Dictionary of the Bible,* vol. iv, pp. 14–16 (1962), with bibliography.

RECIDIVISM. The term recidivism refers to chronic criminal behaviour which results in numerous arrests and incarcerations. Studies of the yearly intake of prisons, reformatories and jails in the United States show that from one-half to two-thirds of those imprisoned have served previous sentences in the same or other institutions. Statistics from European penal institutions come to a similar conclusion. This fact reveals two important facets of the crime problem: one is that the criminal population is made up largely of those for whom criminal behaviour has become habitual, or a way of life; the other indication is that penal institutions do little to change the basic behaviour patterns of their inmates.

Though the percentage of recidivists runs high for both felons and misdemeanants, for the latter group it is far greater. A veritable army of petty offenders appear as repeaters in courts of minor jurisdiction on charges of vagrancy, drunkenness, prostitution, disturbing the peace and other minor offenses. The short jail sentences they usually receive do nothing toward rehabilitation.

The most extensive and reliable studies of persistent criminal behaviour have been made by Sheldon and Eleanor T. Glueck in a series of research monographs of which the first was *Five Hundred Criminal Careers* (1930). These studies revealed the factors in the life situation of recidivists which differentiate them from other prisoners who make a good adjustment after their release from custody.

Among the factors that are more prevalent with the recidivists are poor family situations, broken homes, mothers working outside the home, early onset of delinquency, truancy, poor economic status and adjustment, improper use of leisure and mental deficiency or other personality disorders. Similar factors abound among those offenders who fail to succeed on probation or parole.

It is certain that longer sentences and existing penal methods are no solution to the problem of the chronic offender. Two improvements on current practice would seem to be necessary: one, the adoption of really indeterminate sentences that would enable authorities to keep recidivists in custody until their attitudes change for the better; another essential would be the equipment of penal institutions with personnel and facilities for more thoroughgoing work of rehabilitation. *See* also HABITUAL OFFENDERS; PRISON; PROBATION.

RECIFE (PERNAMBUCO), a city and seaport of Brazil, capital of the state of Pernambuco. Pop. (1960) 788,569, largely Negro and mulatto.

Located at the mouth of the Capiberibe river near the easternmost point of South America, the city is comprised of four separate parts (Recife, Santo Antonio, São José and Boa Vista) which are integrated by many bridges. Because of its numerous waterways the city is often referred to as the "Venice of America."

The district of Recife occupies the southern end of the Olinda peninsula and is the principal commercial centre of the city. In addition to warehouses and terminal facilities, there are the customhouse, observatory, naval arsenal, government offices, several of the consulates and many of the more important banks, business houses and retail stores.

Santo Antonio is located on an island of the same name. Among the important institutions and public buildings in this part of the city are the government palace, the state treasury, the courthouse, the state museum, public library, several fine churches, including the city's famous church of São Francisco de Assís, the Santa Isabel theatre and many historic landmarks, including the Dutch fort of Cinco Pontas.

São José embraces a large district on the mainland and is chiefly residential. In this section of the city is Restoration square, which commemorates the end of Dutch domination.

Boa Vista, also on the mainland, is both a commercial and residential district and contains many of the educational institutions of Recife, including a normal school and schools of law, medicine, engineering, commerce and fine arts.

The hot, humid climate is mitigated somewhat by the southeast trade winds. July, the coolest month, has a mean temperature of 77°, whereas from December through March it is 82°. The total

annual rainfall is 65 in., more than 80% of which falls from March through August.

The port of Recife is one of the most important of Brazil because of its proximity to Europe and its convenience for vessels passing around the east shoulder of the continent. Its harbour consists of a narrow body of water, about 2 mi. in length, which is sheltered on the east by a reef and breakwater. The latter extends about 3,600 ft. in a north and northeasterly direction from the reef—an ancient beach of firmly consolidated materials. A second breakwater (Olinda Mole), about 2,500 ft. in length, runs in a southeasterly direction from the mainland and forms the other wing of the entrance channel. The distance between the heads of these two breakwaters is about 900 ft. The northern part of the harbour is approximately 1,600 ft. in width and has been dredged to a low water depth of 32 ft. The southern part is considerably smaller and has been dredged to a depth of 25 ft. The quay is along the eastern margin of the peninsular district of Recife. The port is equipped with a modern coaling plant and grain conveyor, a sugar conveyor and more than 50 electric and steam cranes. Three sets of tracks, which connect with the Great Western of Brazil railway, serve the wharf and warehouses. There are several concrete warehouses, a cold storage warehouse, a warehouse for commodities which create a public hazard and tanks for petroleum products and alcohol. The terminal facilities are operated by a state *directoria* under the authority of the federal government. The principal imports of Recife are coal, petroleum and wheat. Exports consist largely of sugar, cotton and other agricultural products.

More than 1,600 mi. of railways serve the states of Pernambuco, Alagoas, Paraíba and Rio Grande do Norte, having outlet through Recife, and a well-developed system of surfaced roads provides additional transportation facilities. The city is served by several national and European airlines, has national and international cable connections and radio, telegraph and telephone communications.

Recife was settled in 1535, when Duarte Coelho Pereira landed there to take possession of the captaincy granted him by the Portuguese crown. The site of Coelho's capital was Olinda, but Recife remained its port and did not become an independent *villa* (town) until 1709.

Down to the close of the 18th century, when Rio de Janeiro became important, Recife was the second city of Brazil and for a time its most important port. It was captured and plundered in 1595 by the English privateer James Lancaster. It was also captured by the Dutch in 1630 and remained in their possession till 1654, during which time the island of Santo Antonio was occupied and the town greatly improved. At the end of the Dutch war the capital was removed from Olinda to Recife, where it has since remained. (R. E. P.)

RECIPROCATING ENGINE: *see* STEAM; INTERNAL-COMBUSTION ENGINE.

RECIPROCITY, a term applied to special international treaties or agreements in which mutual concessions in tariff rates, quotas, or other commercial restrictions are granted. If these mutual concessions are neither intended nor expected to be generalized to other countries with which the contracting parties have commercial treaties, the agreement is frequently called a reciprocity arrangement. In addition to the commercial reciprocity treaties between pairs of countries such as those between the United States and Canada (1854), the United States and Hawaii (1875), and the United States and Cuba (1902), there are also reciprocity treaties between groups of countries. The complex of preferential tariff rates applicable to the self-governing members of the British Commonwealth embody reciprocity. The development of a full customs union, which eliminates by progressive mutual concessions all tariffs and other restrictions between participating countries, is the logical extension of reciprocity. Thus the European Economic Community, the European Free Trade Association, and the Latin-American Free Trade Area are examples of customs unions involving special concessions among the parties which are not generalized to other countries.

Membership of the General Agreement on Tariffs and Trade (GATT) runs to some extent counter to the establishment of reciprocity treaties. This is because a nation joining GATT undertakes the obligation to grant to all other members "most-favoured-nation" treatment, whereas a reciprocity treaty is an exclusive agreement between the contracting parties to make mutual trade concessions to each other. For a reciprocity treaty to be permissible for a GATT member, it would have to be extended to all GATT members and would be both difficult to implement and difficult to recognize as a "reciprocity" treaty. *See* TARIFF.

(J. R. HU.)

RECKLINGHAUSEN, FRIEDRICH DANIEL VON (1833–1910), German pathologist who contributed significantly to expanding that science, was born in Gütersloh, Westphalia, on Dec. 2, 1833. He received his degree in medicine at Berlin in 1855 and spent the next six years as assistant to Rudolf Virchow. This was the period of Germany's emergence as the centre of medical progress. Recklinghausen became professor of pathology at the University of Königsberg in 1865, accepted the chair at Würzburg the following year, and in 1872 became the first professor of pathology at the University of Strasbourg. He resigned the professorship in 1906 and died on Aug. 26, 1910.

Recklinghausen's name is perpetuated in the eponyms for two diseases he described. Multiple neurofibromatosis, a condition in which there are numerous fibrous tumours of the skin distributed along the course of the cutaneous nerves, has been called Recklinghausen's disease since his description of it in 1882. Similarly, a generalized fibrosis and cystic degeneration of the skeleton, caused by a hyperfunctioning tumour of the parathyroid gland, is known as Recklinghausen's disease of bone. The smallest lymph channels in connective tissue are known as canals of Recklinghausen.

See H. Bailey and W. J. Bishop, *Notable Names in Medicine and Surgery* (1959). (L. M. Z.; X.)

RECKLINGHAUSEN, a town of West Germany in the *Land* (state) of North Rhine-Westphalia, Federal Republic of Germany. It is on the northern edge of the Ruhr industrial region, 15½ mi. (25 km.) NE of Essen by road. Pop. (1961) 130,581. Although it is an important coal mining and industrial town, the old centre is still preserved, with St. Peter's Church (founded in 1247, mainly 16th century) and remains of fortifications. Chemicals, machinery, metals, and textiles are produced. The *Ruhrfestspiele* (festivals) are held annually in June and July. Recklinghausen was a Saxon settlement which under Charlemagne became an imperial town. From 1236 it passed under the archbishop of Cologne, its territory becoming known as the Vest Recklinghausen. From 1316 it was a Hanseatic town. After 1803 it passed to the duke of Arenberg, who from 1815 held it as a fief of Prussia.

RECLAMATION OF LAND: *see* LAND RECLAMATION.

RECLUS, ÉLISÉE (1830–1905), French geographer and anarchist who was awarded the gold medal of the Paris Geographical society in 1892 for *La Nouvelle Géographie universelle,* was born the second son of a Protestant pastor on March 15, 1830, at Sainte-Foy-la-Grande (Gironde). He was educated at the Protestant college of Montauban and studied geography under Carl Ritter in Berlin. Having identified himself with the republicans of 1848, he was obliged to leave France after the *coup d'état* of Dec. 1851. He spent the years 1852–57 visiting the British Isles, the United States, Central America and Colombia. Returning to France, he applied himself to geography, publishing *La Terre, description des phénomènes de la vie du globe,* 2 vol. (1867–68; Eng. trans., 4 vol., 1871–73) and *Histoire d'un ruisseau* (1869). During the siege of Paris (1870–71) he participated in A. Nadar's balloon ascents. Serving in the national guard in defense of the commune, he was taken prisoner in April 1871; but his sentence of transportation for life was commuted in Jan. 1872 to one of perpetual banishment after European scientists had appealed to the government on his behalf. After a visit to Italy, he settled at Clarens, Switz.

His great work, *La Nouvelle Géographie universelle, la terre et les hommes,* 19 vol. (1875–94; Eng. trans., *The Earth and Its Inhabitants,* 1878–94), is a stupendous compilation, profusely illustrated with maps, plans and engravings and characterized by

the accuracy and brilliance of exposition that give his work permanent scientific value. His *Histoire d'une montagne* was published in 1880. Though benefiting under the amnesty of 1879, Reclus had meanwhile lost none of his revolutionary enthusiasm; and in 1882 he initiated the Anti-Marriage movement, in accordance with which he allowed his two daughters to marry without civil or religious sanction. When proceedings were instituted at Lyons against the International Workingmen's association, P. A. Kropotkin (*q.v.*) and Reclus were designated as leading promoters of anarchism; but Reclus, as domiciled in Switzerland, escaped imprisonment. In 1892 he was appointed professor of comparative geography in Brussels. He died at Thourout, near Bruges, on July 4, 1905. His other works include *L'Homme et la terre,* 6 vol. (1905–08) and several anarchist pamphlets.

RECOGNITION, DIPLOMATIC. This term may refer either to the procedure by which a new state is formally accepted by other states as a member of the international community, or to the procedure by which a new government of an existing state is accepted as the legal representative of that state. The two procedures, although frequently confused, raise distinct legal questions. The recognition of a new state involves the sovereignty of the state and its independent position in relation to other states; the recognition of a new government merely involves the determination of the particular organized group that is to be accepted as having the right to speak in the name of the state, without raising any issue of the legal personality of the state.

While the term "recognition" has been applied to states already enjoying independent existence but not maintaining diplomatic relations with the western powers, as in the case of Ethiopia until its admission into the League of Nations in 1923, its more normal application is to colonies or dependencies that have declared their independence of the mother country and have proved their ability to maintain their separate existence, as in the case of the recognition by the United States of the Latin American states beginning in 1822. The provisions of the United Nations Charter concerning "the self determination of peoples" and the administration of "nonself-governing territories" support such recognitions.

On occasion, political motives have led to the recognition of a new state before it actually proved its ability to maintain its independence, as in the case of the recognition of the United States by France in 1778. Recognition by the Netherlands came in 1782 on the eve of the treaty of peace. After that treaty, the United States was in due time recognized by other states, as by Sweden, Spain and Prussia in 1783, by Portugal in 1794 and by Russia as late as 1809. Premature recognition has regularly been regarded as an offense that the mother country might resent, as Mexico resented the recognition of Texas by the United States in 1837 and Colombia, that of Panama in 1903.

During the 19th century the great powers gave collective recognition to certain new states before they had as yet won their independence by arms, as when Greece was recognized in 1827, Belgium in 1831, and Rumania, Serbia and Montenegro in 1878. Since the close of World War I recognition has frequently been given by voluntary act of the mother country or more recently by collective act of the members of the United Nations. Great Britain, for example, recognized the independence of Ireland in 1920, of Egypt in 1922, and of India and Pakistan in 1947. Recognition by other states followed promptly. Indonesia was recognized by the Netherlands as independent in 1949, and Ghana and Malaya by Great Britain in 1957, followed by their admission to the UN. Many new African nations received recognition in the early 1960s.

The "Stimson doctrine" declared by the United States secretary of state in 1932, and subsequently supported by the League of Nations, asserted that recognition should not be extended to new states or to territorial changes effected by illegal use of armed force. In accordance with this doctrine the United States and the members of the League of Nations refused to recognize the Japanese-supported state of "Manchoukuo" and the United States refused to recognize the Italian conquest of Ethiopia (1936) and the German conquest of Austria (1938).

In the case of new governments the procedure of recognition is applied only when an existing *de jure* government is overthrown by revolution and it becomes necessary for the governments of other states to decide whether the new government has the stability required to justify holding it responsible for the obligations of the state and is entitled in turn to claim the rights of the state. Recognition in such cases raises no question of the legal personality of the state or of its place in the community of nations, but merely the question whether a particular group can properly speak in the name of the state. Governments actually in power are described as *de facto* until such time as recognition by other states makes them *de jure.*

In addition to stability, the condition has frequently been put that the new government must not have been established by immoral behaviour, such as assassination, and must manifest an intention to observe the rules of international law. Such political or subjective conditions of recognition have given rise to numerous controversies and conflicting practices, the new government being recognized by some states and not by others. The United States, for example, refused to recognize the government of Gen. Victoriano Huerta established in Mexico by assassination of President Madero in 1913, and, until 1933, the Soviet government of Russia established by revolution in 1917. The U.S. also refused to recognize the Communist government of China established in 1949 and recognized by many states but continued to recognize the Nationalist government of China on the Island of Formosa. The U.S., however, promptly recognized the government of Iraq established by assassination of King Faisal II in 1958. During World War II the United States and Great Britain refused to recognize the governments of the countries occupied by the German armies and continued to recognize the refugee governments.

Efforts have been made to establish rules of international law on the subject of recognition in addition to the prohibitions of "premature recognition" and "non-recognition of the forces of aggression," but the political element of recognition has dominated and states have been unwilling to accept a collective decision applying law on a matter on which diametrically opposite points of view may be taken with respect to the conduct that may be expected of the new government.

(C. G. FK.)

RECOGNIZANCE, in Anglo-American law, is an obligation entered into before some court or judicial officer (judge or magistrate) whereby the party bound (the recognizor) acknowledges that he owes (generally to the government) a stated sum of money, subject, however, to the condition that he will not owe the sum if he does (or, sometimes, does not do) a specified act. The recognizor may be required to furnish sureties. If he fails to perform the specified act, the amount stated is a debt (sometimes said to be more nearly a judgment than a debt) which may be collected in an appropriate legal proceeding.

The recognizance device serves various purposes. Its most common use is in connection with bail in criminal cases; a person arrested for a crime may generally secure his release from imprisonment pending his trial (or, sometimes, pending his appeal after trial and conviction) by filing in court a recognizance (sometimes termed a bail bond), generally with money or property posted as surety, undertaking to pay a stated amount unless the accused appears in court for further proceedings at a specified time. Where no surety is required, the accused is said to be released "upon his own recognizance." In the United States a material witness, imprisoned to ensure his presence at the trial at which his testimony is needed, may similarly secure his release by filing his recognizance, often with sureties required. In the United Kingdom a witness may not be imprisoned for this purpose. One who threatens to injure or kill others may be arrested and brought into court and released upon his recognizance (perhaps with sureties) to keep the peace. In civil litigation the recognizance of a party may be required to ensure the payment of costs (*i.e.,* amounts of money which losing parties must pay to winning parties as reimbursement for expenses of litigation).

See BAIL; CRIMINAL LAW. (A. W. ST.)

RECONSTRUCTION FINANCE CORPORATION. The Reconstruction Finance corporation in the United States was established by congress on Jan. 22, 1932, "to provide emergency financing facilities for financial institutions, to aid in financing agriculture, commerce and industry." After a few years of unprecedented depression and steady price declines, an institution was required which could pump dollars into financial institutions, railroads, etc., to enable them to meet their commitments. The RFC in turn was to obtain dollars from the federal government. In moderating the epidemic of bankruptcies in the 1930s, the RFC helped lay the groundwork of recovery. The RFC was to operate as an independent agency, not subject to political influences. Every application would be considered on its merits, not on political considerations. It was also generally assumed that loans would be made on the condition that private financing was not available and that an important public interest would be served.

In the early years Jesse Jones, chairman of the board of directors, managed the institution without much interference. But as the functions of the RFC grew, and particularly as the RFC, even in the 1930s, began to assume responsibility for disbursing huge sums of money for other government agencies, without the delays incident to the voting of funds through the appropriation committees of the congress, the agency tended to become involved in politics.

By the 1940s the situation had become precarious. The Hoover commission in 1949 noted that "direct lending by the government to persons or enterprises opens up dangerous possibilities of waste and favoritism. . . . It invites political and private pressures, or even corruption" (*Report on Federal Business Enterprises*, March 31, 1949). As early as 1948 a congressional committee (Senate Committee Report no. 974 on the RFC act) had noted that attempts to influence the business judgments of RFC by the use of political influence, even though well intended, were a constant menace to sound administration. In a report in 1951, the senate banking and currency committee (Report no. 649) complained of the increasing practice of applicants seeking direct access to the directors of the RFC through members of the Democratic national committee; and many cases of corruption were aired.

Despite this, the Democratic majority of the banking and currency committee in 1951 proposed only to correct abuses, not to destroy the RFC, for the majority emphasized the important financing contributions of the RFC in a financial market that was imperfect at best. Once the Republicans came into power in 1953, however, they provided for a quick liquidation of the RFC (RFC Liquidation act, July 30, 1953). Effective June 30, 1957, the RFC was abolished and its remaining functions transferred to the Housing and Home Finance agency, the General Services administration, the Small Business administration and the treasury department.

During 21 years and 8 months of RFC lending, more than $12,000,000,000 was disbursed. When, in Sept. 1953, its lending authority was terminated, it had $800,000,000 outstanding in loans, securities and commitments. Aside from its peacetime activities, the RFC under legislation in 1940 and 1950 had assumed large military responsibilities; *e.g.*, purchases of strategic items, building of plant facilities. (S. E. H.)

RECONSTRUCTION PERIOD (U.S.), a term used in U.S. history to denote the years immediately following the American Civil War (1861–65). The reconstruction of the 11 seceded states that had made up the Confederate States of America grew out of the attempt to find acceptable solutions to peculiar political, economic, and social problems that had been raised by secession and war. The political problem was essentially a matter of restoring Southern state governments to what President Lincoln had termed their "proper relation" to the Union. The economic problem was one of adjustment to the economic revolution that was transforming a prewar agrarian nation into a postwar industrial nation. The social problem was centred around the question of the status of the newly freed slaves. As these problems involved basic questions of authority and jurisdiction, it was perhaps inevitable that any serious attempt to solve them would lead to conflict between the president, the Congress, and the individual states. The process of readjustment was further complicated by certain regional problems that were born of victory and defeat. The victorious North faced such complex problems as demobilization, conversion of wartime industry to peacetime production, and restoration of civil law in areas recently under military control. In the South, defeat and demoralization were aggravated by physical devastation, shortages of food in certain critical areas, inadequate transportation facilities, and a growing spirit of lawlessness that accompanied the paralysis of local government. (*See* UNITED STATES [OF AMERICA]: *History: Civil War and Reconstruction 1850–1876.*)

Presidential Reconstruction.—Some steps toward the reconstruction of Southern states were taken by the executive department of the government before the end of the war. First under Lincoln and later under Andrew Johnson, presidential programs of remarkable leniency were inaugurated. Lincoln's plan was put into effect during the war in areas occupied by Federal forces. In December 1863 the president issued a proclamation embodying his "ten per cent plan," which provided for the reestablishment of a state government whenever 10% of the voting population of 1860 had taken the prescribed oath of allegiance. Put into effect in Louisiana, Tennessee, Virginia, and Arkansas, the plan had slowly evolved from Lincoln's experiences with the border states and with military governments set up in occupied areas and from his own changing concept of the nation. It was, in substance, an invitation to the Southern people to reorder their political structure and take up their places in the new nation that had supplanted the old Union. Based upon the assumption that reconstruction of a state government was exclusively an executive function and that it was solely a political affair, the plan precipitated a bitter struggle between the president and the Radical wing of his own party in Congress. Once the Radicals had grasped the fact that Lincoln's program did not include social and economic reconstruction of the South, they began to challenge his control and direction of the machinery of reconstruction. Their own more stringent program was embodied in the Wade-Davis Bill passed in July 1864. Lincoln, hoping to "reanimate the states" under presidential supervision before Congress reconvened, killed the Wade-Davis Bill by means of a pocket veto. The assassination of Lincoln in April 1865 elevated Andrew Johnson of Tennessee to the presidency. Johnson, a Southern Unionist who had been elected vice-president on the Lincoln ticket in 1864, continued Lincoln's moderate program with only minor modifications. In so doing, he alienated the Radicals just as Lincoln had, and when Congress reconvened in December 1865, the Radicals were again prepared to challenge presidential control of reconstruction. On the first day of the new session the struggle was begun when the Congress, after refusing to seat the "Confederate Brigadiers" who had been elected in the South, created the Joint Committee on Reconstruction. The climax of this struggle between the executive and legislative branches of government was reached in the election of 1866 when both sides attempted to win popular support for their programs. Johnson's own intemperate outbursts against the opposition, coupled with such reactionary developments within the South as the rejection of the 14th Amendment (except by Tennessee, which was readmitted in 1866), race riots in Memphis and New Orleans, and passage of repugnant "Black Codes" (restricting the freedom of the Negroes) by Johnson-supported state governments, seriously weakened the president's position and helped the Radicals win a smashing victory in the election. With what now appeared to be a mandate from the voters in states that participated in the election, the Radicals in Congress abruptly took over control of the reconstruction process from the executive.

Congressional Reconstruction.—Congressional control of the reconstruction experiment was assured by passage of the Reconstruction Acts of March 1867 that were specifically designed to undo the work of Lincoln and Johnson. As a result of these acts, the ten remaining Southern states were divided into five military districts, each commanded by a major general of the U.S. Army. These officers were to supervise the reconstruction of the states in their respective districts until such time as a new constitution

could be drawn up and approved by Congress. With the Southern states thus firmly in hand, the Radicals further strengthened their legislative hegemony by impeaching President Johnson (who escaped conviction by the margin of one vote in the Senate), badgering the Supreme Court into temporary submission, and by placing Gen. Ulysses S. Grant in the White House by the election of 1868.

Reconstruction in the South.—Under the supervision of the U.S. Army, Southern voters were registered, delegates to constitutional conventions selected, constitutions drafted, and local officials elected. Between June 1868 and July 1870 the ten remaining states were all readmitted to the Union through the processes outlined in the congressional program of Reconstruction. These newly created state governments were generally Republican in character and were governed by political coalitions of Negroes, "carpetbaggers" (Northerners who went into the South), and "scalawags" (Southerners who collaborated with the Negroes and "carpetbaggers"). Because these Republican state governments were looked upon as artificial creations that had been imposed from without, the conservative element in the South remained hostile to them. Southerners were particularly resentful of the activities of the Freedmen's Bureau, a federal agency specifically created to help the Negro adjust to his new situation, and the Union League, an organization that had originated in the North during the war and had moved into the South in the immediate postwar period where it became the most effective agency for inculcating the newly enfranchised Negro with Republican principles.

This resentment led to the formation in the South of secret terroristic organizations, the most powerful of which was the Ku Klux Klan (*q.v.*). Several other organizations such as the Knights of the White Camelia, the Palefaces, and the White Brotherhood were also employed as instruments of violence. Continual opposition from within the South led eventually to the overthrow of the congressionally sponsored state governments that had been set up once civilian rule was reestablished. Through the deliberate use of fraud, violence, and intimidation, Southern conservatives regained control of their state governments and by 1877, when Federal troops were withdrawn from Louisiana—the last Southern state to be "redeemed"—the Democratic Party had been returned to power in each Southern state.

Significance of the Reconstruction Period.—The Reconstruction era left an indelible imprint on the history of the United States. It fixed firmly on the national scene that economic revolution that had been begun during the war and was destined to make possible the remarkably rapid transformation of an essentially agrarian society into what was to become modern, industrial America. It introduced a number of worthwhile reforms into the South. Courts were reorganized, judicial procedures improved, new and improved techniques of school administration were instituted, and more feasible methods of taxation devised. Many of the state constitutions adopted during the postwar years are still in existence. It is also true that the Reconstruction experience led to an increase in sectional bitterness, to an intensification of the racial issue, and to the development of one-party politics in the South.

RECORDER, an English judicial office originating with the creation of courts of quarter sessions for boroughs, about the 16th or 17th century. Originally one of several judges, the recorder became the sole judge of criminal cases tried before borough quarter sessions. There are three full-time, permanent recorders: one for London, who sits in the Central Criminal Court, and one each for Manchester and Liverpool. Other recorderships are part-time, honorific posts, held by eminent practising barristers.

The title has been used elsewhere to designate judges of other criminal courts and, in the United States, has been most frequently used as a title for the government official in charge of keeping records, such as a recorder of deeds.

See JUDICIARY AND COURT OFFICERS. (P. B. K.)

RECORDER, a musical instrument of the flageolet class, also described as "fipple flute" from the shape of the part which the player holds to the lips. Most modern recorders, made since the instrument's revival by Arnold Dolmetsch in 1919, follow the early 18th-century or Baroque design: the cylindrical head joint is partially plugged to direct the wind against the sharp edge below; the body tapers and its lowest part is usually made as a separate foot joint; there are seven finger holes and one thumbhole. Often the lowest two holes are each arranged as a pair of holes, one of which is left open to produce the semitone above the note made by covering both. The upper register, at the octave, is obtained by "pinching" the thumbhole; *i.e.*, flexing the thumb to make a narrow opening above the thumbnail. The larger instruments may have one or more keys, allowing holes to be pierced at points otherwise out of reach of the fingers. Recorders are made in the following sizes: sopranino in f″; descant (soprano) in c″; treble (alto) in f′; tenor in c′; bass in f; and (rarely) great

17TH- AND 18TH-CENTURY RECORDERS

(Left) French 17th-century ivory recorder. (Right) Set of recorders by P. J. Bressan, 18th century: from left to right, treble in f′, alto (voice flute) in d′, tenor in c′, and bass in f. The supporting strut, at far right, is inserted into a socket at the bottom of the bass recorder, to rest it on the floor

bass in c. (These notes refer in each case to the instrument's lowest note.) The treble and tenor recorders sound at written pitch; the sopranino and descant sound an octave higher than written; the bass, the music for which is written in the bass stave, also sounds an octave higher.

The recorder is a 14th-century improvement upon kindred instruments played earlier in the Middle Ages. The English name may derive from Old Italian *ricordo*, a keepsake. The first instructions are found in the books by Sebastian Virdung (1511) and Sylvestro Ganassi (1535), written at a time when recorder consorts were approaching the height of their popularity. The Baroque repertory, which includes many works by Handel and Bach, is almost exclusively for treble recorder (then described as "flute" or "common flute"), after which time the instrument lay obsolete until its flourishing modern revival. (A. C. BA.)

RECORDING, PHONOGRAPH: *see* PHONOGRAPH.

RECTIFIER, a device which converts one or more alternating-current waves into a unidirectional wave. It may be an electron tube (of either vacuum or gaseous type), vibrator, barrier-layer cell, or mechanical device. Although they often serve the same purposes, rotary converters and motor-generator sets are not usually classified as rectifiers.

If an alternating-current wave is applied to the diode vacuum tube, the resulting output is a succession of pulses similar in shape to the positive portions of the input wave but separated from each other by an amount of time corresponding to the negative portions of the input wave. This is termed half-wave rectification.

Two diodes may be connected in such a manner that one will conduct when the other does not. This type of operation, called full-wave rectification, results in a continuous train of pulses.

Both the half-wave and full-wave rectifier outputs may be smoothed by inserting a capacitor across the output.

Gaseous tube operation in rectifier applications is quite similar to that of the vacuum tube but the power capabilities are much greater.

Copper-oxide rectifiers, consisting of a layer of cuprous oxide on a copper disk, and selenium rectifiers, consisting of a layer of selenium on iron, are examples of the barrier-layer types. In both cases, the boundary (barrier-layer) offers relatively low resistance to the passage of current in one direction but very high resistance to current in the other direction.

Regardless of the form it may take, the rectifier's fundamental property is one of unidirectional conductivity.

See also AMPLIFIER, ELECTRONIC. (A. L. Sy.)

RECTO, CLARO MAYO (1890–1960), Philippine statesman and unsuccessful presidential candidate, was born in Tiaong, Tayabas (now Quezon) Province, on the island of Luzon. From 1919 to 1928 he served as a member of the Philippine House of Representatives and floor leader of the minority Democrata Party. Elected to the Senate in 1931, he joined the Nacionalista Party two years later and in 1934 was chosen president of the Constitutional Convention. He served for one year on the Supreme Court of the Philippines (1935–36) and was reelected to the Senate in 1941.

After the outbreak of World War II, he stayed in the Philippines and held various government positions under the Japanese. He was returned to the Senate for six-year terms in 1949 and 1955. Although defeated for the presidency in 1957, he was highly esteemed for his brilliance as a lawyer and man of letters. He staunchly advocated "respectable independence" in foreign relations and a domestic policy of vigorous economic nationalism popularly called "Filipino First." He died Oct. 2, 1960, in Rome. (C. A. B.)

REDBRIDGE, one of the 32 London boroughs constituting Greater London, Eng., forms part of its northeastern perimeter and is bounded south by the borough of Newham, south and east by Barking, northeast by Havering, north by Essex, and west by Waltham Forest. This outer London borough was established on April 1, 1965, under the London Government Act 1963 (*see* LONDON) by the amalgamation of the former boroughs of Ilford and Wanstead and Woodford, and parts of Dagenham and of the urban district of Chigwell. Area 21.8 sq.mi. (56.5 sq.km.). Pop. (1965 est.) 247,960. Redbridge returns three members of Parliament and elects three members on the Greater London Council. The Wanstead and Woodford constituency was represented (1924–64) by Sir Winston Churchill, who is commemorated by a statue (1959) on Woodford Green. Redbridge is mainly residential and within its boundaries are 730 ac. (30 ha.) of Epping Forest. Industry includes light engineering, and the manufacture of radio and electric components, photographic materials, and chemicals. The borough is served by the Central Line of the London Underground, and the Eastern Region of British Rail.

Wanstead (Wenesteda), Woodford (Wdefort), and Ilford (Ilefort) are mentioned in the Domesday Book. Ealdford is a Saxon description of Ilford, and Hyleford and Yleford are other recorded spellings probably referring to the village near the ford across the River Roding (Saxon Hyle).

In Saxon times both manors of Wanstead and Woodford were held by the king. St. Edward the Confessor gave Wanstead to the Abbey of Waltham Holy Cross; Harold II bequeathed Woodford to Westminster Abbey. Robert Dudley, earl of Leicester, entertained Queen Elizabeth I at Wanstead House (demolished in 1824) which James I gave with the manor to the duke of Buckingham. Sir Charles Bright, the telegraphic engineer, was born in Wanstead in 1832, Thomas Hood (1799–1845), the poet, lived at Lake House, and R. B. Sheridan (1751–1816) also lived in the district; William Morris (1834–1896) lived for a time at his father's home Woodford Hall (since demolished). The River Roding which flows through Woodford was crossed by the Red Bridge from which the borough derives its name. (K. F. B. N.)

REDCAR, a municipal borough in the Cleveland parliamentary division of the North Riding of Yorkshire, Eng., on the northeast coast 8 mi. (13 km.) ENE of Middlesbrough. Pop. (1961) 31,460. Area is 8.1 sq.mi. (21.0 sq.km.). Lying midway along the continuous stretch of sand between the Tees estuary and Saltburn, it serves as residential town and holiday resort for the industrial population of south Tees-side. It was incorporated in 1922. Huge industrial developments on its western boundaries include chemical works, a steel rolling mill, and docks on the borough's frontage to the Tees River.

Kirkleatham Hall, in the lovely village of Kirkleatham, was the home of the Turner family from the 17th century until 1948 after which it was demolished.

RED CROSS, an international humanitarian agency with national affiliates in almost every country in the world, was originally established to care for the victims of battle in time of war. The scope of its program has gradually expanded to include aid to prisoners of war and other victims of hostilities and also the prevention and relief of human suffering in time of peace as well as war. The emblem of the Red Cross (the Red Crescent in the Muslim countries and the Red Lion and Sun in Iran) identifies personnel and installations entitled to protection during hostilities.

ORIGIN

The Battle of Solferino between the French and Italians and the Austrians took place on June 24, 1859. Jean Henri Dunant of Switzerland, then aged 31, was a witness of the suffering of thousands of wounded men for whom medical and nursing care was lacking. In the nearby town of Castiglione he did what he could, with the help of the local inhabitants, to organize assistance for the wounded who had been brought there. In 1862 he published "A Memory of Solferino," describing the terrible aftermath of the fighting and proposing that in every country relief societies should be formed in peacetime that would be recognized and ready to succour the wounded in time of war. The wide interest generated by his proposal led to the formation of a committee in 1863 which later became the International Committee of the Red Cross. At a meeting called by this committee in Geneva on Oct. 26–29, 1863, and attended by delegates from 14 countries, the basic principles of the Red Cross were formulated.

The first Red Cross Convention, drawn up at a diplomatic conference in Geneva the following year, committed signatory governments to care for the wounded of war, whether enemy or friend. In later years this first convention was revised and improved, and new conventions were adopted to protect victims of warfare at sea (1907), prisoners of war (1929), and civilians in time of war (1949).

THE RED CROSS MOVEMENT

The worldwide structure of the International Red Cross consists of three components: (1) the International Committee of the Red Cross (Comité International de la Croix-Rouge); (2) the League of Red Cross Societies; and (3) the national Red Cross societies. An international conference, held every four to six years, includes representatives not only of these three groups, but also of the governments that adhere to the Geneva Conventions.

International Committee of the Red Cross.—The International Committee is an independent council of 25 Swiss citizens with headquarters at Geneva. One of its functions is to accord recognition to new national Red Cross societies following inquiry

concerning their structure and purpose. Its activities in wartime stem from its original concern for those wounded in battle, but have responded to modifications resulting from the changed conditions of combat. Among these developments have been visits and services to prisoners in war camps and the channeling of information about them to their families. In World War II, for example, a card index was maintained showing the location of millions of prisoners and civilian internees, thousands of visits were made to prison camps, relief supplies were provided, and letters were forwarded to the prisoners. Exchange of wounded prisoners among belligerents was also arranged.

Since direct communication among belligerent countries is blocked in wartime, the Committee acts as an intermediary not only among these governments but also among their national Red Cross societies. This role enabled it, during World War II, to make appeals to the warring nations not only in behalf of war victims but also with respect to improved implementation of the international conventions.

The dislocations and the suffering caused by war extend far beyond the cessation of hostilities. The Committee therefore concerns itself with the relief of starvation and the alleviation of distress caused by war both during and after the period of active conflict. After World War I, for example, it arranged for the repatriation of 450,000 prisoners of war. In World War II, in collaboration with the League of Red Cross Societies, it created the Joint Relief Commission which distributed food, clothing, and pharmaceuticals among civilian war victims.

From a long-range point of view the Committee's most important contribution relates to the extension and improvement of the international conventions relating to the protection and care of the victims of war. The period following World War II has been dedicated to the revision and improvement of the existing conventions and to the preparation of a new one for the protection of civilians in time of war. In 1917 and again in 1944 the International Committee was awarded the Nobel Peace Prize.

League of Red Cross Societies.—France, Great Britain, Italy, Japan, and the United States were the first members of the League of Red Cross Societies, which was established in 1919. Growth of the League has increased the number of national member societies to more than 100, with an aggregate junior and adult membership of almost 200,000,000. Each member society has a representative on the League's board of governors.

The purposes of the League are to serve as a means of communication among the national societies, to coordinate international relief work, and to protect mankind by stimulating peacetime programs for the improvement of health, the prevention of disease, and the relief of suffering. A secretariat with headquarters in Geneva carries on the work of the League, maintaining for this purpose technical departments on disaster relief, health, nursing and social service, and Junior Red Cross. Through its relief bureau, the League coordinates rescue work in catastrophes in which the scope of the disaster exceeds the resources of a national government and its relief agencies. The health bureau provides materials for health education and promotes the extension of health work by the national societies. The nursing bureau, established in 1919, was extended in 1951 to include a social service section. This bureau conducts an information service, selects and counsels candidates for Red Cross scholarships, and provides guidance to national societies in establishing Red Cross nursing schools and training programs for nurses' aides and teachers of home nursing. The Junior Red Cross bureau assists the junior sections, organized largely in elementary and secondary schools by the national societies in 75 countries throughout the world. A major objective of the junior sections is the promotion of friendship and understanding among children of different races and cultures.

From time to time the League arranges regional conferences in different sections of the world to enable national societies to exchange views concerning problems common to the countries in that area. It also maintains continuing liaison with international organizations whose programs are related to Red Cross objectives, including the World Health Organization, the International Refugee Organization, and others.

National Red Cross Societies.—Among the requirements a national society must meet to gain recognition by the International Committee are: (1) the government of its country must have adhered to the Geneva Conventions; (2) it must adopt the name and emblem of the Red Cross (except that in Muslim countries the Red Crescent and in Iran the Red Lion and Sun are used); (3) its activity must extend throughout the country and its dependencies; (4) membership must be open to all its citizens regardless of race, sex, politics, or religion; (5) it must agree to maintain contact with the other national societies and with the International Committee at Geneva, and must be guided in all its work by the spirit of the Geneva Conventions. Only one national Red Cross society is recognized in each country and, within its own territory, each is autonomous.

The first national Red Cross societies to come into existence—the Belgian, French, Italian, and Spanish (all 1864)—followed immediately on the Geneva Conference of 1863. A hundred years later more than 100 national societies were in existence. The American National Red Cross was organized in 1881 with Clara Barton, a volunteer worker on the battlefields of the Civil War, as its first president; altogether 30 societies were founded in the 19th century and an additional 7 before the outbreak of World War I. Another 26 were founded before the beginning of World War II and a further 39 after World War II. In the 1960s 22 societies were to be found in Africa (16 Red Cross, 6 Red Crescent), 23 in North and South America, 25 in Asia (18 Red Cross, 6 Red Crescent, and one Red Lion and Sun), 2 in Australasia, and 30 in Europe (29 Red Cross and one, U.S.S.R., an alliance of the Red Cross and Red Crescent).

The wartime activities of national societies have included such diverse services as providing ambulances, hospitals, and medical and nursing personnel; operating canteens for troops in transit; distributing food in occupied territories; donating comfort items to hospitalized combatants and to civilian victims of war; locating families and friends displaced by the hostilities; and conducting major programs of relief for refugees and for civilian populations impoverished by war. (A. W. M.)

Peacetime Activities.—The scope of the peacetime activities of Red Cross societies has increased enormously since the end of World War I, covering many aspects of health and welfare. Many societies have large-scale first-aid programs, including education in accident prevention, swimming and water safety, beach and highway first-aid stations, emergency ambulance services, and mountain rescue teams. A number of societies train nurses' aides, visiting housekeepers, and mothers' assistants, and maintain maternal and child welfare centres and clinics, such as those of the Iranian Red Lion and Sun and the infants' clinics of the Guatemalan Red Cross. The Indian Red Cross trains midwives. Some societies specialize in work with handicapped children; for instance, the Australian Red Cross has a service for spastic children, the British society works a great deal with the deaf and dumb, and the Swedish Red Cross runs summer camps, not only for the physically disabled but also for the mentally retarded. These services are largely carried out, under supervision, by specially trained Junior Red Cross members. School hygiene is emphasized by many societies and some operate summer colonies, preventoria, and homes for orphans and deserted children. A number of societies have services for the aged, the lonely, and the isolated, with Junior Red Cross members often visiting the blind in these categories.

Members and former members of the armed forces and their families are given financial aid, counseling, referral, and other services. Particularly in the U.S., Australian, and Philippine societies, help for former servicemen and their dependents includes assistance in establishing veterans' claims for government benefits, retraining the disabled, supplying orthopedic appliances, etc.

Maintaining hospitals, clinics, and dispensaries are the major programs of many societies, particularly in Latin-American countries; there, and in Lebanon, mobile clinics are often used for rural work. The training of nursing personnel varies from the postgraduate training provided by the French Red Cross to that conducted by the British Red Cross for voluntary auxiliary aides for civil defense. The enrollment of nurses and auxiliary personnel for

ambulance, pharmaceutical, radiological, poliomyelitic, and tuberculosis work is an activity of many societies. Public health nursing services are also conducted, and the Swiss Red Cross runs a comprehensive health centre in the canton of Geneva. Health education is likewise a part of Red Cross activities, including campaigns against tuberculosis, poliomyelitis, cancer and venereal diseases, and "Health in the Home" courses, conducted by more than 50 national societies. An auxiliary service in this connection is the medical loan depot, run by some societies, including the British and Swedish, to provide equipment for those sick at home.

Procurement of blood and the maintenance of blood banks are other activities of many Red Cross societies. Outstanding examples of comprehensive blood programs are those of the U.S. and Canadian societies. Outpost work is featured by many societies, such as the visiting housekeepers for isolated areas furnished by the Australian Red Cross, which also has teams standing by in case of bush fires or floods, the first-aid posts and clinics of the South African society, and the air ambulances of the Swedish Red Cross. Among less common activities are the Belgian Red Cross "Spéléo-Secours" for emergency cave rescue work; the French Red Cross Airborne Nurses services; the Italian Red Cross special emergency ambulance service on highways; the Netherlands Red Cross hospital ship, the "J. Henri Dunant," used to give outings to the chronically ill and isolated; the Norwegian Red Cross Prison Visitors Service and home for discharged prisoners; the Swiss society's centre for Tibetan refugees in Switzerland; and the Thai Red Cross "Snake Farm" for the production of antisnakebite serum, which is sent all over the world.

REDDITCH, an urban district on the eastern boundary of Worcestershire, Eng., 19 mi. (31 km.) NE of Worcester by road. Pop. (1961) 34,151. It lies on a ridge about 500 ft. (152 m.) above sea level in a pastoral setting. In the mid-1960s Redditch was designated for development as a New Town with a population of 70,000, to relieve congestion in the Birmingham area. North of Redditch are the scanty remains of Bordesley Abbey, a 12th-century Cistercian foundation. Needles and fishing tackle are the principal industries and springs, bicycles, and motorcycles are also manufactured. Redditch is connected by rail to Birmingham (15½ mi. [25 km.]) and Alcester (8 mi. [13 km.]). It is in the Bromsgrove parliamentary division.

REDEMPTION, in religion, has both a larger association and a more limited biblical context. In the first sense it is broadly identified with salvation, atonement (*q.v.*), reconciliation, and forgiveness. It refers to the action of God within history whereby mankind has been delivered from sin and death through the life, death, and resurrection of Jesus Christ (*see* Jesus Christ). "In him we have redemption through his blood, the forgiveness of our trespasses according to the riches of his grace" (Eph. 1: 7). The biblical metaphor is that of buying back a parcel of land or of purchasing someone from slavery. In the Old Testament redemption is usually described as deliverance from material disasters, but in Ps. 130 it is promised that God "will redeem Israel from all his iniquities." Jesus' saying that "the Son of man also came not to be served but to serve, and to give his life as a ransom for many" (Mark 10:45) found its deepest expression in his crucifixion.

Emphasis has been placed on the voluntary and loving character of Christ's sacrificial act, on the costliness of this deliverance, on the representative and substitutionary activity of Christ in doing for men what they could not do for themselves, and on the needed response of men in faith, worship, and newness of life to this initiative of God in Christ.

REDEMPTORISTS (Congregation of the Most Holy Redeemer; Congregatio Sanctissimi Redemptoris; C.SS.R.), a religious congregation founded by St. Alfonso Maria de' Liguori (*q.v.*) at Scala, Italy, Nov. 9, 1732. Benedict XIV granted papal approbation Feb. 25, 1749. Neapolitan regalism was an obstacle to the congregation, and steps were taken to settle also in the papal states. In 1785 through St. Clement Hofbauer (*q.v.*) the congregation entered the transalpine world, and eventually secured foundations throughout Europe and, during the centenary year, 1832, the United States. The congregation now is established on the five continents. The purpose of the congregation is the sanctification of the members through the imitation of Jesus Christ and the preaching of the word of God, especially to the poor, through various means, particularly parish missions. The Redemptorists also conduct parishes and foreign missions.

The congregation, composed of priests, clerical students, and lay brothers, is ruled by a superior general, who is elected for life and resides in Rome at the general mother house. He is aided by general consultors who represent geographical areas. Provincials, vice-provincials, and rectors are appointed by him. There is also an order of Redemptorist nuns, founded by St. Alfonso Liguori in 1731 and approved in 1750. *See* Orders and Congregations, Religious.

See M. de Meulemeester, *Outline History of the Redemptorists* (1956); G. Stebbing, *The Redemptorists* (1924).

REDFIELD, ROBERT (1897–1958), U.S. anthropologist, developed concepts that brought into a single purview preliterate tribes, folk peasantries, and complex civilizations. Born Dec. 4, 1897, in Chicago, he was associated all of his life with the University of Chicago, as student, professor, and dean. The son of a lawyer, Redfield married Margaret Park (daughter of the sociologist Robert E. Park) before graduating in law. A summer visit to Mexico turned him to anthropology. His Ph.D. dissertation (1928) reported field work in a community in Mexico; *Tepoztlan* received immediate attention as a pioneer study of the "folk" community as a way of life. After extended field work with his family in Yucatán, he showed through comparison of tribe, village, town, and city how the growth of a small isolated community into a large heterogeneous society involves social disorganization and the substitution of formal institutions for a "moral order." Later, study of the civilizations of China and India, which he visited, suggested how the intellectual-aesthetic "great tradition" alters the character of small communities and their continuing "little traditions." Peasants are seen as living in small part-societies, somewhat tribal-like but affected by cities and the great tradition.

Redfield died on Oct. 16, 1958, in Chicago.

Among his writings are *Tepoztlan* (1930); *Chan Kom* (1934); *The Folk Culture of Yucatan* (1941); *A Village That Chose Progress* (1950); *The Primitive World and Its Transformations* (1953); *The Little Community* (1955); *Peasant Society and Culture* (1956). His *Papers*, two volumes (1962–63), were edited by Mrs. Redfield.

See Fay-Cooper Cole and Fred Eggan, "Robert Redfield," in *American Anthropologist*, vol. lxi, no. 4 (Aug. 1959); "Robert Redfield," *National Cyclopaedia of American Biography*, vol. 44 (1962).

(S. Tx.)

REDLANDS, a city of San Bernardino County, Calif., U.S., is situated at the foot of the San Bernardino mountains, 65 mi. (105 km.) E of Los Angeles. (For comparative population figures *see* table in California: *Population.*)

The city lies at the upper end of San Bernardino valley at an elevation of 1,200 to 2,100 ft. (366 to 640 m.), surrounded by peaks more than 10,000 ft. (3,000 m.) high. While the navel orange-growing area has been its basic economy, Redlands also provides

homes for military and civilian personnel who work at nearby Norton and March Air Force Bases and the local rocket company. Within easy commuting distance of Los Angeles, the nearby beaches, mountain resorts, and desert playgrounds, with a mild sunny climate, Redlands is an ideal residential town.

The University of Redlands, affiliated with the American Baptist Convention, was established in 1907. The Watchorn Lincoln memorial stands on the grounds of the public library. The San Bernardino *asistencia* (chapel), rebuilt by the historical society, represents a link with the city's Spanish heritage, and the Redlands Music Association provides weekly summer concerts in the Prosellis Bowl.

The present city was founded in 1887 by New Englanders and incorporated in 1888. While retaining "Yankee" characteristics, it is representative of all areas of the country. A council-manager system of government was adopted in 1949.

(G. B. Be.)

REDLICH, JOSEPH (1869–1936), Austrian historian, jurist, and politician, an authority on English and Austrian administration and parliamentary development and on comparative law, where his exhaustive knowledge of Austrian, English, and American institutions was of especial value. Redlich was born in Göding (Hodonin), Moravia, on June 18, 1869. He studied jurisprudence and history at Vienna, where he became professor in 1906. His first book was published in 1901, *Die englische Lokalverwaltung* (Eng. trans. *Local Government in England,* 1903) and he followed this in 1905 with *Recht und Technik des englischen Parlamentarismus* (Eng. trans. *The Procedure of the House of Commons,* three volumes, 1907), a standard work on the subject. In a parallel field he wrote *Das Wesen der österreichischen Kommunalverfassung* (1910), on Austrian local government; and *Österreichische Regierung und Verwaltung im Weltkriege* (1925; Eng. trans. *Austrian War Government,* 1929). He also wrote a biography of Francis Joseph I (1928). The most important of his books on Austria, however, is the great unfinished *Das österreichische Staats- und Reichsproblem* (two volumes, 1920–26), a history of domestic policy from 1848. Redlich's third sphere of interest was American. In 1914 he published *The Common Law and the Case Method in American University Law Schools,* and in 1929 he became professor of comparative law at Harvard and head of the university's new Institute of Comparative Law.

Redlich was a politician as well as a scholar, sitting in the Moravian Diet and in the *Reichsrat* until 1918. He was minister of finance from October to November 1918 and returned from the United States to take the same portfolio in the Buresch cabinet in 1931. He died in Vienna on Nov. 12, 1936. (M. Kl.)

REDMAYNE, SIR RICHARD AUGUSTINE STUDDERT (1865–1955), British engineer and an authority on mining who was instrumental in formulating the safety regulations embodied in the Coal Mines Act (1911), was born near Gateshead-upon-Tyne, Durham, on July 22, 1865. He trained at the Hetton collieries and worked for two years in Natal, before returning to England in 1893 to become manager of the Seaton Delaval collieries. In 1902 he was appointed professor of mining at the newly established University of Birmingham. In 1908 he became HM chief inspector of mines and, during World War I, assistant controller of coal mines. He served on many committees dealing with safety in mines and was chairman of the Imperial Mineral Resources Bureau and of the Advisory Council on Minerals to the Imperial Institute, of which he was for a time acting director. Redmayne was awarded the companionship of the Order of the Bath in 1912 and promoted to knight commander in 1914. He was president of the Institution of Mining and Metallurgy (1916–17), of the Institution of Civil Engineers (1934), and, for 33 years, of the Institute of Professional Civil Servants. Among his writings are *Men, Mines, and Memories* (1942) and *The Problem of the Coal Mines* (1945). He died at Little Hadham, Herts., on Dec. 27, 1955. (C. W. D.)

REDMOND, JOHN EDWARD (1856–1918), Irish nationalist leader who devoted his life to the cause of Home Rule for Ireland, was born at Ballytrent, County Wexford, on Sept. 1, 1856, the son of William Archer Redmond, M.P. for Wexford. In 1874 he entered Trinity College, Dublin, to read law, but left in 1876, when his father required his assistance in London, and he became a clerk in the House of Commons. He was called to the Irish bar in 1886 and to the English bar at Gray's Inn in 1887. Elected to Parliament for New Ross in February 1881, he created a record by taking his seat, making his maiden speech, and being suspended from the House, all within 24 hours. A fervent admirer of Charles Stewart Parnell, Redmond soon became a whip to his party. By his eloquence and practical arguments he gained for the policy of Home Rule many converts in Great Britain, and on political missions to Australia (1882) and the United States (1884) he collected large funds from Irish sympathizers.

When the Irish Nationalist Party split after the Parnell divorce scandal in November 1890, Redmond became the leader of the small minority which supported Parnell. In 1891 he was elected as a Parnellite member for Waterford, which he represented until his death. In 1900 the two sections of the Irish party were reunited and the larger section agreed to accept Redmond as leader. At first he was unable to exert a decisive pressure upon the rival English parties; only when they were equally divided could he hold the balance of power between them (*see* Ireland: *History*). The first opportunity occurred in 1909 when the rejection of Lloyd George's radical budget by the House of Lords created a constitutional crisis. In both the elections of 1910 a Liberal ministry was returned dependent upon Irish Nationalist support, in return for which a third Home Rule Bill was introduced in April 1912.

The passage of the bill seemed assured until the Unionists in Ulster adopted new tactics by organizing an armed defiance of Parliament. Their leader, Sir Edward Carson, planned to form a provisional government in Belfast and early in 1913 enrolled an armed Ulster volunteer force. Redmond's whole life had been spent in the House of Commons and such defiance of its authority seemed to him incredible. When he discovered that a rival force of Irish volunteers were enrolling in Dublin in November 1913, he saw that there was a real danger of civil war and that the Irish volunteers, under untried leaders, might disregard constitutional methods. As a result of his efforts the movement was, in June 1914, placed under more responsible and representative leaders.

By March 1914 Redmond had reluctantly agreed that for a brief period those northeastern counties which voted against it should be excluded from Home Rule. The Ulster Unionists, however, demanded exclusion for all nine countries of Ulster. The outbreak of World War I in August 1914 imposed a sudden truce in these disputes and the Home Rule Bill was passed, though with a suspensory bill delaying its operation until the end of the war. Redmond made a dramatic speech in the House of Commons on Aug. 3 in which he declared that the Irish and English democracies had common aims and that Ireland would give full support to the Allied war effort. However, his proposal that the home defense of Ireland should be entrusted jointly to both forces of volunteers was ignored, and his efforts to recruit Irish brigades for service overseas were hampered by anti-Irish influence in the war office in London.

A split occurred among the Irish volunteers in September 1914 and the small extreme republican section actively opposed Ireland's participation in the war. The insurrection in Dublin on Easter Monday, 1916, took Redmond by surprise and shattered his whole policy. Attempts to find a settlement were made by the prime minister, H. H. Asquith, and by Lloyd George, but without success. Redmond served actively in the Irish Convention which met in Dublin to devise a new constitution in July 1917. By the beginning of 1918, however, it had almost reached deadlock. In February he went to London, where his health, which had been failing rapidly, now broke down and he resigned from the leadership of the party. After an operation he died in London on March 6, 1918, and was buried at Wexford.

REDON, ODILON (1840–1916), French Symbolist painter, lithographer and etcher, was born in Bordeaux on April 20, 1840. An early friendship with the botanist Armand Clavaud stimulated his tastes in literature and philosophy and encouraged his love of

drawing. He studied for a short time with Jean Léon Gérôme in Paris, but it was a meeting with the vagabond artist Rodolphe Bresdin in Bordeaux which had the greatest influence on him. During a life which was passed almost in retirement he produced 172 lithographs, 26 etchings and many paintings and drawings which are the testimonials of his sincerity, integrity and unselfish dedication to his art. The largest collection of his prints is in the Art Institute of Chicago. Due to his friendship with the poet Stéphane Mallarmé and the character of his work he is associated with the Symbolists. He died in Paris on July 6, 1916.

See André Mellério, *Odilon Redon* (1923). (H. Es.)

REDONDA: *see* ANTIGUA.

REDONDO BEACH, a resort city in Los Angeles county, Calif., U.S., is situated 19 mi. S.W. of Los Angeles on the Pacific ocean. Once seriously considered for the port of Los Angeles, Redondo Beach was developed in the 1880s with an iron pier and a narrow-gauge railroad. Though it was a commercial port for some years while San Pedro was being developed, its wide beaches and sharp palisades were tourist attractions, and promoters took advantage of its natural beauty by building fine hotels, a salt-water plunge, amusement facilities and an interurban rail line with Los Angeles. The city was incorporated in 1892 and adopted the city-manager form of municipal government in 1949. After 1945, the beach city also became a residential community for many people working in the oil refineries of Torrance, Wilmington and El Segundo. It has a public library, a symphony orchestra and a light-opera association. El Camino college (1948) and Loyola university (1911) are nearby. King harbour provides excellent boating facilities. For comparative population figures *see* table in CALIFORNIA: *Population.* (J. A. Sz.)

RED RIVER, a river of southeast Asia, rises in Yünnan Province, China, and flows southeastward for about 311 mi. (500 km.) across North Vietnam to the Gulf of Tongking, east of Hanoi. The Red is the principal river of North Vietnam, and the plain formed by its delta is the most extensive and one of the richest agricultural areas in the country, though frequently plagued by flooding. The reddish colour of the river is caused by the approximately 130 million metric tons of silt carried downstream each year.

RED RIVER, sometimes called Red River of the South to distinguish it from the Red River of the North (*q.v.*), is formed in the high plains of the Texas panhandle. It flows generally eastward into Arkansas, where it turns southeast through Louisiana to its junction with the Old river, which connects the Mississippi with the Atchafalaya river. Though the Red is considered a tributary of the Mississippi, much of its normal discharge goes directly to the gulf by way of the Atchafalaya.

The Red is 1,018 mi. long; for about half this distance it serves as the Texas–Oklahoma boundary. Among the many tributaries are the North Fork of the Red, Kiamichi, Little and Black (Ouachita) rivers.

Early navigation of the Red above Natchitoches, La., prior to 1832 was impeded by a jam of driftwood almost 160 mi. long. Capt. Henry M. Shreve cleared this "great raft" to Oklahoma by 1837. A later raft which formed above Shreveport was cleared in 1873. After removal of these rafts navigation prospered for a time, with Alexandria and Shreveport, La., being the chief beneficiaries. Though Fulton, Ark., 455 mi. upstream, is now considered the head of navigation, vessels drawing over four feet can reach it only a few months of the year. Most of the 1,000,000-ton annual traffic is in the lower 35 mi. portion.

In the early 1940s Denison dam was completed on the Red 726 mi. above the mouth. This multipurpose dam forms Lake Texoma, a 223-sq.mi. lake with a storage capacity of 5,530,000 ac.ft. (M. W. M.)

RED RIVER OF THE NORTH, formed by the juncture of the Bois de Sioux river from the south and the Otter Tail river from the east at the twin cities of Wahpeton, N.D., and Breckenridge, Minn. It flows north, forming the North Dakota–Minnesota boundary, then crosses the U.S.–Canadian border and enters Lake Winnipeg 40 mi. N. of Winnipeg, Man. The distance from its source to its mouth is 320 mi. but the river winds in such intricate curves over the flat plain of former glacial Lake Agassiz that the actual river mileage is 545 mi. It has cut a gorge 20 to 50 ft. deep through clay deposits throughout the greater part of its course. The principal tributaries from the west are the Assiniboine, Sheyenne, Wild Rice (of North Dakota) and Pembina rivers; from the east are the Otter Tail, Red Lake, Wild Rice (of Minnesota) and the Roseau rivers.

The river drains an agricultural region that is famous for the production of cereal grains, potatoes, sugar beets and livestock. Important recreation areas are found on the margins of the basin. The leading cities on the river are Winnipeg, and Fargo and Grand Forks, N.D. (B. L. W.)

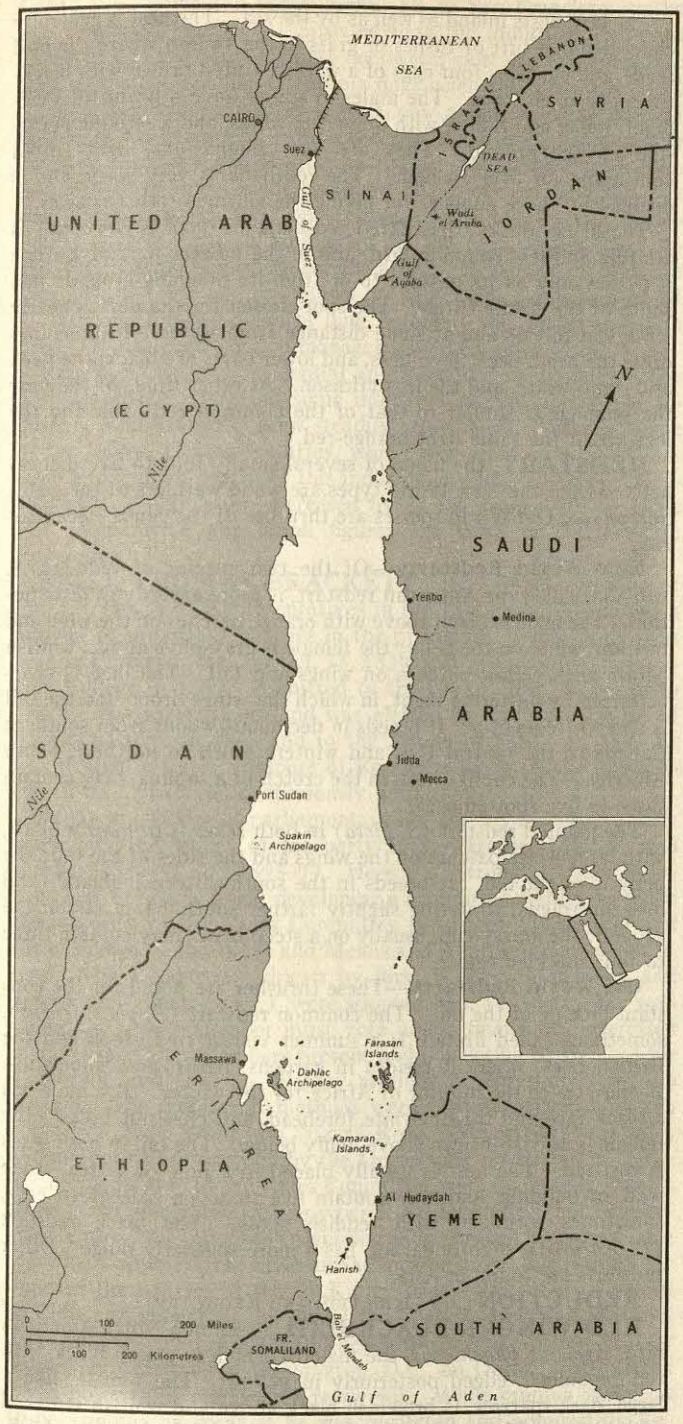
RED RIVER SETTLEMENT, a Scottish colony founded in 1811 near the present city of Winnipeg by a philanthropic Scottish nobleman, Lord Selkirk, who at that time controlled the Hudson's Bay Company and received from it a grant of 116,000 sq.mi. in the basin of the Assiniboine and Red rivers. Quarrels soon arose with the French and half-breed employees of the North West Fur Company, and were fostered by its officials. On June 19, 1816, in a fight between the rivals, Governor Semple of the Hudson's Bay Company and 19 of his attendants were killed, an affair known as the Battle of Seven Oaks. New settlers were sent by Selkirk and founded the village of Kildonan, now part of Winnipeg. In 1821 the rival companies united, and in 1836 repurchased from Selkirk's heirs all rights to the territory. In 1821 and in 1835 two forts, known as Lower and Upper Ft. Garry, were built to command the junction of the Red and Assiniboine rivers.

The purchase in 1869 of the territorial rights of the company by the dominion of Canada caused the Métis of the settlement great uneasiness, and under their leader, Louis Riel (*q.v.*), they set up a provisional government. This was dispersed by troops from Canada in August 1870 and the government of the new province of Manitoba was established.

BIBLIOGRAPHY.—J. J. Hargrave, *Red River* (1871); George F. G. Stanley, *Birth of Western Canada* (1936, 1961); Vera Kelsey, *Red River Runs North!* (1951); W. L. Morton, *Manitoba: a History* (1957); E. E. Rich (ed.), *Hudson's Bay Company, 1670–1870* (1960).

RED SEA, a narrow strip of water extending south-southeast from Suez to the Strait of Bab el Mandeb in a nearly straight line, and separating the coasts of Saudi Arabia and Yemen from those of Egypt, Sudan and Ethiopia. The Red Sea was so named because of a free floating form of blue-green algae (*Trichodesmium erythraeum*) which has a red accessory pigment and occasionally gives a red colour to the surface waters. Its total length is about 1,200 mi. (1,900 km.), and its breadth varies from about 250 mi. (402 km.) in the southern half to 130 mi. (209 km.) in 27° 45′ N, where it divides into two parts, the Gulf of Suez and the Gulf of Aqaba, separated from each other by the peninsula of Sinai. Structurally, the Red Sea is part of a great rift-valley system forming one of the most marked features of the earth's crust. The rift valley of the Jordan and the Dead Sea is continued southward by the Wadi el Araba, and its submerged southern section gives the Gulf of Aqaba. This well-marked north-northeast to south-southwest line meets the north-northwest to south-southeast line, already marked in the Gulf of Suez, and together they form, to the south, the main basin of the Red Sea. The rift may be traced still farther southward among the great African lakes.

This great structural depression is probably of Tertiary age, being let down between two ancient Archean blocks—Arabia and north Africa. Secondary and Tertiary deposits appear on both flanks in Egypt and Arabia, while Archean material appears at the surface in many places on the Red Sea coast. These extensive earth movements were accompanied by much volcanic activity, traces of which are still evident. A group of volcanic islands occurs in 14° N, and on Jebel Teir, near 15°30′ N, jets of steam still appeared in the second half of the 20th century. The margin of the Red Sea itself consists, on the Arabian side, of a strip of low plain backed by ranges of barren hills of coral and sand formation, and here and there by mountains up to 6,000 ft. (1,800 m.) and more in height. The greater elevations are for the most part formed of limestones, except in the south, where they are largely volcanic. The coasts of the Gulf of Aqaba are steep, with numer-



THE RED SEA

ous coral reefs on both sides. On the African side there are, in the north, wide stretches of desert plain, which toward the south rise to elevated tablelands, and ultimately to the mountains of Ethiopia. The shores of the Red Sea are little indented; good harbours are almost wanting in the desert regions of the north, while in the south the chief inlets are near 15° N at Massawa, and at Kamaran, almost directly opposite. Coral formations are abundant; immense reefs, both barrier and fringing, skirt both coasts, often enclosing wide channels between the reef and the land.

Depths.—The mean depth of the Red Sea is approximately 1,611 ft. (491 m.) and its area and volume are approximately 169,100 square miles (437,969 sq.km.) and 52,000 cubic miles respectively. The Gulf of Suez is shallow, with a maximum depth of about 210 ft., and outside its mouth the bottom in the Red Sea slopes rather steeply to a depth of about 4,140 ft. at 27°30′ N. The Gulf of Aqaba attains a depth of 4,200 ft. in 28°39′ N and 34°43′ E. Its deeper waters are separated from the deep water of the Red Sea by an entrance sill much of which is considerably less than 600 ft. below the surface. Along the mid-line of the Red Sea an irregular trough about 30 mi. broad between the 3,000-ft. depth contours extends from 27°30′ N to 17° N where it is interrupted by a transverse submarine ridge rising to within 1,200 ft. of the surface. Between 25° N and 17° N mid-channel depths occasionally exceed 7,200 ft., with a maximum of over 9,000 ft. reported near 20° N, whereas to the south the maximum depth is about 4,020 ft. and the channel shoals to about 300 ft. off Hanish Island in crossing the entrance sill which separates the deeper basin of the Red Sea from that of the Gulf of Aden. From the north end of the Red Sea to the banks of Suakin and Farasan in 20° N the 600-ft. line keeps to a belt of coral reef close inshore, but in lower latitudes the shallow coral region, 300 mi. long and 70 to 80 mi. across, extends farther and farther seaward until at 15° N, off Hodeida (Al Hudaydah), the part of the channel that is deeper than 600 ft. is only 20 mi. broad, all the rest of the area being dangerous to navigation even for small vessels. The Strait of Bab el Mandeb, the southern entrance to the Red Sea, is divided by Perim Island into two channels. The eastern channel is 1.7 mi. broad between the 30 ft. curves and has a maximum depth of 96 ft. The western channel preferred for navigation, is 1,020 ft. in mid-channel and is 10.4 mi. wide between Perim Island and the islands near the African coast.

Meteorology.—In the northern part, down to almost 19° N, the prevailing winds are north and northwest. The middle region, to 14°–16° N, has variable winds in an area of low barometric pressure, while in the southern Red Sea southeast and east winds prevail. From June to August the northwest wind blows over the entire area; in September it retreats again as far as 16° N, south of which the winds are for a time variable. In the Gulf of Suez the prevailing wind is northerly or northwesterly, but the westerly or "Egyptian" wind occurs occasionally during winter, sometimes blowing with violence, and generally accompanied by fog and clouds of dust. Strong north-northeast winds prevail in the Gulf of Aqaba during the greater part of the year; they are weakest in April and May, sometimes giving place at that season to southerly breezes. The mean monthly air temperature ranges from 71° F (22° C) at Suez to 86° (30°) at Massawa. Rainfall is light, generally less than an inch a year along the northern shores, and nowhere exceeding about ten inches. At some points a year may pass without a trace of rain. The high temperature and great relative humidity in summer make it a difficult region for active life.

Water Temperature.—The mean annual surface temperature of the waters varies from about 75° F (24° C) near the head to 80° F (27° C) in about 22° N, to 84° (29° C) in 16° N, and drops again to 82° (28° C) at the Strait of Bab el Mandeb. Temperatures in February are about 5° below and in August 5° above the annual mean. Temperature is, on the whole, higher near the Arabian than the Egyptian side. During summer the temperature decreases rapidly, dropping as much as 10° in the upper 150 ft. and then decreasing more slowly to about 70.7°, in water at depths of 600 to 1,200 ft.; this latter temperature is constant throughout the sea and the year. In winter as a consequence of increased density caused by rapid evaporation and cooling, sinking of surface water apparently occurs north of about 22° N, and the temperature changes but slightly with depth. In the southern part of the area, however, the temperature still decreases with increasing depth, but because of surface cooling the drop is less pronounced than in summer. In the Gulf of Suez temperatures are relatively low, ranging from about 64° in February to 79° in August, and decreasing quite rapidly from south to north. The waters in the Gulf of Aqaba are reportedly warmer toward the Arabian than the Sinai coast, but here as well as in the Red Sea proper temperatures will vary locally in response to wind and circulation patterns; a uniform temperature of 70.2° is observed in the deeper water.

Salinity.—The salinity of the waters is very high compared to that found in the open ocean, the surface values being highest, $41^0/_{00}$ (per mille), in the Gulf of Suez, and decreasing to about $36.5^0/_{00}$ near Perim Island at the southern entrance. Below a

depth of 600 ft. the salinity ranges between 41$^0/_{00}$ in the north and 40.5$^0/_{00}$ in the south. South of about 20° N the salinity increases with depth, the increase being particularly rapid between 300 and 600 ft., whereas in the north, there is little change from top to bottom. In general the surface salinity is somewhat greater on the western than the eastern side. In the Gulf of Aqaba the salinity is quite uniform averaging about 40$^0/_{00}$. Salinities of 50$^0/_{00}$ to 55$^0/_{00}$ are encountered in the Bitter Lakes section of the Suez Canal, but the prevailing current carries most of this water toward the Mediterranean.

Circulation.—The movements of the waters are of great irregularity and complexity, rendering navigation difficult and dangerous. Two features stand out with special distinctness; the exchange of water between the Red Sea and the Indian Ocean, and the tidal streams of the Gulf of Suez. During the north-northwest winds of summer surface water and a layer of highly saline bottom water flows from the Red Sea to the Gulf of Aden, and between these layers a contrary current of Indian Ocean water sets into the Red Sea. In winter surface waters enter the Red Sea from the Gulf of Aden but Red Sea water continues to discharge at depth. The water carried by the bottom current was formed and sank in the northern part of the Red Sea in winter and has a high salinity and temperature and a low concentration of dissolved oxygen. Through these characteristics it has been traced at intermediate depths in the Indian Ocean south past the equator. In the Gulfs of Suez and Aqaba, almost the only part of the Red Sea in which tidal phenomena are well developed, a sharply defined tidal circulation is found. Elsewhere, the surface movements at least are controlled by the prevailing winds, which give rise in places to complex transverse currents, and near the coast are modified by the channels enclosed by the coral reefs. During the prevalence of the north and northwest winds the surface level of the northern part is depressed by as much as two feet.

The Red Sea was important in Egyptian maritime commerce at least as early as the 2nd millennium B.C. and it had associations with India early in the 1st millennium B.C. Under the Arabs the Red Sea was an important highway of trade with connections to India, Persia and East Africa. This sea helped to keep Islam in touch with the thinkers of the East and with the glories of the ancient world during the dark ages in the West; with the revolutions in shipping and movement by sea that followed the age of discovery the Red Sea seemed to retreat into the background; but with the cutting of the Suez Canal (1869) and the shortening of the route to India, Australia and the East, the Red Sea not only recovered its former importance but became one of the greatest commercial highways in the world.

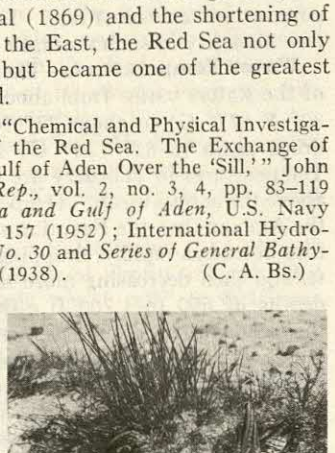
REDSHANK, the name of a snipelike bird, *Totanus totanus*, so-called from the colour of its long legs. In suitable localities it is abundant throughout the greater part of Europe and Asia, retiring southward for the winter, though a considerable number remain along the coasts of some of the more northern countries. The body of the redshank is as big as a snipe's, 11 in., but its longer neck, wings, and legs make it appear larger. Above, the general colour is grayish, freckled with black, except the lower part of the back and a conspicuous band on each wing, which are white, and the flight-quills, which are black. The long, straight bill is reddish with a black tip.



ERIC HOSKING

REDSHANK (TOTANUS TOTANUS) ON NEST

The bird nests inland as well as by the sea. The nest is generally concealed in a tuft of rushes or grass in the swamp where the bird feeds, and contains four eggs of a warmly tinted brown with blackish spots or blotches. The males in spring have a beautiful song-flight, rising and falling with quivering wings, and a striking courtship on the ground. They are very pugnacious, fights often continuing for over an hour. The redshank is very wary, and is disliked by shore gunners for giving the alarm to other species.

The black, dusky, or spotted redshank (*Tringa erythropus*) is a larger and less common bird, and in the greater part of Europe it occurs only on its passage to or from its breeding-grounds just south of the Arctic Circle. The spot chosen for the nest is nearly always in forests and at some distance from water. In breeding-dress the head, neck, shoulders, and lower parts are black, the back and rump white, and the legs crimson. At other times of the year the plumage is similar to that of the common redshank and the legs are of the same light orange-red.

REDSTART, the name of several small (four to five inches) active birds: the New World types are wood warblers of the genus *Setophaga;* Old World species are thrushes of the genus *Phoenicurus.*

New World Redstarts.—Of the two species of redstart, *S. ruticilla*, called the American redstart, is more easterly in distribution. The male is black above with orange patches on the wing and tail, and white on the belly; the female is gray-olive above, whitish below, with yellow patches on wings and tail. The bird is characterized by fluttering flight, in which the wings droop and the tail is spread frequently. It breeds in deciduous woods from southern Canada to the central U.S. and winters south to northern South America. The cuplike nest, in the crotch of a sapling, may contain three to five spotted eggs.

The painted redstart (*S. picta*) in both sexes is primarily black, with large white patches on the wings and the sides of the tail; the belly is bright red. It breeds in the southwestern highlands and into Nicaragua, wintering slightly farther south. It nests on the ground; the grassy cup, usually on a steep bank, may contain three to four speckled eggs.

Old World Redstarts.—These thrushes are noted for the constant flicking of the tail. The common redstart (*P. phoenicurus*), sometimes called firetail, is a summer visitor to Europe and the British Isles, where it resides in gardens, parks, and woodlands. It migrates to the interior of Africa for the winter. The male has a black face and throat, white forehead, and chestnut breast; the female is grayish-brown above, buffy below. The tail in both sexes is rust-red. The nest is usually placed in a hole of a tree, stone wall, or building, and may contain five to seven pale green eggs, sometimes sprinkled with reddish spots. The black redstart (*P. ochruros*), slightly darker, has a more southerly range. Other redstarts are found in Asia.

REDUCTION: *see* OXIDATION AND REDUCTION.

RED-WINGED BLACKBIRD, a common North American bird, *Agelaius phoeniceus*, the male of which is glossy black with red "epaulets" edged posteriorly in yellow. The female, like a large, dark sparrow, is brownish black above and whitish streaked with black and brown below; the wing coverts are faintly reddish. Both sexes are about eight inches long. This species, the most widely distributed member of the family Icteridae, comprises 14 subspecies breeding from Mexico to central Canada and Alaska; some subspecies are resident; others tend to move into the southern part of their range for the winter. These noisy, gregarious birds, with liquid song and shrill alarm call, often fly in flocks and nest chiefly in groups in swamp or bushland. Their diet during the breeding season consists mainly of insects; later in the year grain and other seeds are also eaten. The well-built cuplike nests, suspended on reeds or other vegetation, may contain three to five pale bluish eggs marked with dark spots or scribbles.

Related are the tricoloured blackbird (*A. tricolor*) of the West Coast, with conspicuous white margin to the epaulet; the tawny-shouldered blackbird (*A. humeralis*) of Cuba and Haiti; and the yellow-shouldered blackbird (*A. xanthomus*) of Puerto Rico.

REDWOOD: *see* SEQUOIA.

REDWOOD CITY, a city and the seat of San Mateo County,

Calif., U.S., is located about 27 mi. SE of San Francisco on the San Francisco Peninsula. Situated near the mouth of Redwood Creek, it has the southernmost deepwater port on San Francisco Bay, used since Spanish-California days when the town was on El Camino Real (historic mission trail, now a federal highway) and known as Embarcadero. Once the site of an early shipbuilding industry that served a flourishing lumber and shingle trade, the port is used mainly for the shipment of oil, cement, and salt. It was first plotted in 1854 on sections of the old Rancho de las Pulgas, largest Spanish land grant in the area, dating back to 1795. Originally named Mezesville after S. M. Mezes, its Mexican founder, the town became known by its present name because of its redwood lumber business long before it was incorporated in 1867. It has been council-manager governed since 1929.

Redwood City is a residential and industrial community. The port has always attracted some industry and the number of industrial establishments grew steadily after World War II. Some of the largest electronics firms, which have made the San Francisco Peninsula a centre of this industry, are located there. Redwood City's population increased by 81.1% from 1940 to 1960. For comparative population figures *see* table in CALIFORNIA: *Population.* (S. B. KN.)

REED, THOMAS BRACKETT (1839–1902), speaker of the U.S. House of Representatives in the 1890s who introduced a number of important changes in the procedure of that body, was born in Portland, Me., on Oct. 18, 1839, and graduated from Bowdoin College in 1860. Admitted to the bar in 1865, he began to practise law in Portland, and was elected to the State House of Representatives in 1868 and to the Senate in 1870. In 1877 he was elected to the U.S. House of Representatives on the Republican ticket and served continuously until 1899.

Reed's knowledge of parliamentary law and his executive ability made him the leader of his party in the House, 1886–89 and speaker, 1889–91 and 1895–99. He was a "strong" speaker in his control over proceedings; developing a committee system, he made the majority of the Rules Committee consist of the speaker and the chairmen of the Ways and Means and Appropriations committees. The Reed rules, drawn by him, William McKinley, and Joseph G. Cannon (*qq.v.*), were adopted Feb. 14, 1890; they provided that every member must vote unless financially interested in a measure, that members present and not voting be counted for a quorum, and that no dilatory motions be entertained by the speaker. His dictatorial methods were bitterly attacked by the opposition, who called him "Czar" Reed. Nevertheless his rules and methods were adopted by the Democratic leadership in 1891–95 and the powers of the Rules Committee were increased. Reed's name is not associated with any particular legislation, but he exercised a powerful influence in guiding bills through Congress. He vigorously opposed free silver and advocated protective tariffs. He opposed the policies of the McKinley administration with regard to Cuba and Hawaii at the end of the Spanish-American War and as a result resigned in 1899 and began the practice of law in New York City. He died in Washington, D.C., on Dec. 7, 1902. Reed was a powerful orator with a ready wit. While opinion varied as to his conduct as speaker, he was respected and admired by Republicans and Democrats as a man of rugged honesty and intense loyalty.

See William Robinson, *Thomas B. Reed, Parliamentarian* (1930). (H. F. TT.)

REED, WALTER (1851–1902), U.S. Army bacteriologist renowned for his work on yellow fever, was born in Gloucester County, Va., on Sept. 13, 1851, and was educated at the University of Virginia and Bellevue Medical School (M.D., 1870). In 1875 he entered the Medical Corps of the U.S. Army as assistant surgeon, with rank of lieutenant. In 1893 he was promoted to surgeon, with rank of major, and was made professor of bacteriology and clinical microscopy in the newly organized Army Medical School at Washington, D.C. When the Spanish-American War began, Reed was appointed chairman of a committee to investigate the causation and mode of propagation of typhoid fever, an epidemic of which had broken out among the soldiers. The committee's *Report on the Origin and Spread of Typhoid Fever in U.S. Military Camps* (published in 1904, after Reed's death) revealed a number of points concerning the disease not before known, and emphasized others that had been little appreciated.

In 1897 Reed and an associate proved erroneous the theory of Giuseppe Sanarelli and others that a bacillus was the specific cause of yellow fever. In 1900, when the disease broke out among U.S. troops in Cuba, Reed was made chairman of a commission to investigate its cause and method of transmission. The other members were James Carroll, Jesse W. Lazear (*q.v.*), and Aristides Agramonte. Reed's observation of many cases led him to discount the then prevalent idea that the disease was transmitted by contact with bedding, clothing, etc., of patients suffering from yellow fever, and to revive the discarded notion of Carlos Juan Finlay (*q.v.*) that the yellow fever parasite was carried only by mosquitoes. Since the disease was not acquired by animals there was no method of proof except by experiment upon human beings. By a thorough set of experiments, in which some of his co-workers sacrificed their lives, Reed proved to a skeptical world that the yellow fever parasite was carried only by the mosquito then called *Stegomyia fasciata* (later classified as *Aëdes aegypti*) and that the bite of this mosquito caused the disease only under certain conditions. Possessed of this knowledge, U.S. sanitary engineers led by Maj. William C. Gorgas (*q.v.*) eradicated yellow fever from Cuba (there was not one case in 1902), and it has since been largely eliminated from those parts of the world where scientific public health procedures are carried on. Reed returned in 1901 to Washington, where he died of appendicitis on Nov. 23, 1902. The army general hospital in Washington was named in his honour.

See H. A. Kelly, *Walter Reed and Yellow Fever* (1923).

REED, a term applied to several distinct species of large, water-loving grasses. The common or water reed, *Phragmites communis,* occurs along the margins of lakes, fens, marshes, and placid streams, not only throughout Great Britain and the United States, but widely distributed in arctic and also in temperate regions, extending into the tropics. Another very important species is *Ammophila arenaria* (also known as *Psamma arenaria*), the sea reed or marram grass, a native of the sandy shores of Europe and North Africa. Both species have been of notable geological importance, the former binding the soil and so impeding denudation, and actually converting swamp into dry land, largely by the aid of its tall (5 to 10 ft.) close-set stems. The latter species, of which the branching rootstocks may be traced 30 or even 40 ft., is of still greater importance in holding sand dunes against the sea, and for this purpose has not only been long protected by law, but has been extensively planted on the coasts of Norfolk, Eng., the Netherlands, Gascony, etc. Other reeds are *Calamagrostis* (various species), *Gynerium argenteum* (pampas grass), etc., also *Arundo donax,* the largest European grass (6 to 12 ft. high), which is abundant in Europe. Reeds have been used from the earliest times in thatching and in other branches of construction, and also for arrows, the pipes of musical instruments, etc. Reed pens are still used in the East. Plants belonging to other orders occasionally share the name, especially the bur reed (*Sparganium*) and the reed mace (*Typha*), both belonging to the family Typhaceae. The bulrushes (*Scirpus*), belonging to the family Cyperaceae, are also to be distinguished.

See also GRASSES.

REED INSTRUMENTS: *see* WIND INSTRUMENTS.

REEL, a type of dance which appears to have originated in Scotland. Early references show that reels were known throughout Scotland in the 16th century, though little is known of their precise form.

During the 17th century the Presbyterian Church in Scotland severely discouraged social dancing, and by 1700 the reel seems to have survived only in the Scottish Highlands, where Presbyterian influence was weakest. After 1700, when the church became more tolerant of dancing, reels reappeared in the Scottish Lowlands, presumably having been reintroduced from the Highlands. From about 1700 to 1770 the only specific reel mentioned in Scottish literature is the Threesome reel, but after about 1770 this was largely superseded by the Foursome reel. In both, and in most other Scottish reels, the dancers repeatedly perform a simple

traveling figure alternated with elaborate steps danced in one place.

Reels of this same form also occur in England and Wales, while a different kind is known in Ireland. There is, however, no evidence to show that these English, Welsh, and Irish reels developed earlier than the late 18th century. The Eightsome reel, included at dances throughout the United Kingdom, does not conform to the usual structure. Composed about 1870, it incorporates the figures of a reel dating from about 1818.

Reel is also the name of a type of dance tune. The earlier reel tunes were simply tunes appropriate to the dances, but after about 1700 reel was used primarily for a fast dance tune in 4/4 time. These common-time reels have almost invariably an insistent semiquaver motion, particularly noticeable at the end of the phrases. *See* also STRATHSPEY; VIRGINIA REEL. (T. M. FL.)

REESE, LIZETTE WOODWORTH (1856–1935), U.S. poet whose poetry is largely based on the rural simplicities of her childhood, was born in Baltimore County, Md., Jan. 9, 1856, and died in Baltimore, Dec. 17, 1935. She spent her childhood on the York Road, near what became the Village of Waverly, in what was then the outskirts of Baltimore. Educated privately, she began to teach in St. John's parish school in Waverly in 1873, and continued teaching in the public schools of Baltimore until her retirement in 1921.

Her lyric talent was strikingly evident even in her first book, *A Branch of May* (1887), and her reputation grew slowly. Her condensed form and sincerity of emotion broke with 19th-century conventional sentimentality and foreshadowed the tone and temper of 20th-century lyricism. The sonnet "Tears," published in 1891 in her fourth collection, *A Wayside Lute,* became deservedly well known. *Selected Poems* (1926) was followed by several other volumes of verse: *Little Henrietta* (1927), *White April* (1930), and *Pastures* (1933); and two books of reminiscences: *A Victorian Village* (1929) and *The York Road* (1931). (LE. BN.)

REEVE, HENRY (1813–1895), English writer, an influential though inconspicuous figure in early Victorian politics, was born at Norwich, Eng., on Sept. 9, 1813, and educated at Geneva, Munich, and Paris. In 1835 he translated Alexis de Tocqueville's *Démocratie en Amérique.*

In 1837 he was nominated head of the legal department of the privy council office, a post he held for 50 years. From 1840 to 1855 he wrote leading articles for the *Times,* and practically guided its foreign policy; friendships with Lords Clarendon and Granville, and with Guizot and Thiers (*qq.v.*), and his trenchant style gave his articles weight. From 1855 he edited the *Edinburgh Review,* contributing most of the articles on foreign affairs himself. His edition of the *Memoirs* of C. C. F. Greville (*q.v.*), in three series (1874, 1885, and 1887), though carefully expurgated, gave much offense. Reeve died near Bournemouth on Oct. 21, 1895.

See J. K. Laughton, *Memoirs of . . . Henry Reeve,* 2 vol. (1898). (M. R. D. F.)

REEVE, a representative of higher governmental authority; in early English history the reeve's function was the effectuation of the king's fiscal rights and the maintenance of the peace, including some minor judicial duties. The title still is used in some places to designate minor government officials of various kinds.

REFERENDUM AND INITIATIVE, two methods by which the wishes of the electorate may be expressed with regard to proposed legislation. They exist in a variety of forms. The referendum may be obligatory or optional. Under the former type certain classes of actions by a legislature are required, ordinarily by constitutional provision, to be referred to a popular vote for approval or rejection. Amendments to constitutions proposed by legislatures are subject in most states of the United States, for example, to an obligatory referendum. Under the optional (or facultative) referendum a specified number of voters by petition may demand a popular vote on a law passed by a legislature. By this means actions of a legislature may be overruled.

The referendum may also be constitutional or legislative depending on the nature of the matter referred. In the United States questions subject to the obligatory referendum are mostly constitutional while those subject to the optional referendum are invariably legislative. The obligatory and optional forms are to be distinguished from the submission by legislative bodies of questions to a referendum or plebiscite, the effect of which may be determinative of the issue or only advisory to the legislature.

By the initiative a specified number of voters may invoke a popular vote on a proposed state or local law or a proposal to amend the state constitution. In its direct form a proposal supported by the requisite number of voters is submitted directly to a popular vote for decision. Under the indirect form the legislature has an opportunity to enact such a proposal. If rejected, the proposition is submitted to a popular vote, in some instances with an alternative proposal by the legislature or with a statement of its reasons for rejection.

The initiative and referendum came into common use in Switzerland in the liberal reaction after the Paris revolution of 1830. In 1831 St. Gall first adopted the facultative referendum (then and for some time after called the veto), and its example was followed by several cantons before 1848. The obligatory referendum appeared first in 1852 and 1854, but in its modern form it was first adopted in 1863 by the canton of rural Basel. The initiative was first adopted in 1845 by Vaud. Both institutions have been used freely in federal and cantonal matters.

Swiss experience with the devices of direct legislation was influential in the adoption of the initiative and the optional referendum in U.S. states and municipalities.

The United States.—The obligatory referendum on amendments to state constitutions proposed by state legislatures, first adopted by Connecticut in 1818, was in the second half of the 20th century the prevailing method for the amendment of state constitutions. In some states a referendum is obligatory on bond issues and a like rule is widespread in local government for bond issues, tax questions and related matters. Because of the detailed nature of state constitutions and the necessity for their frequent amendment, many issues not of a nature to arouse great interest among the voters are referred to them for amendment.

In U.S. usage, the terms initiative and referendum or direct legislation refer not to the obligatory referendum but to the optional referendum on legislation and to the initiation of laws or constitutional amendments by the voters (with the assumption that a popular vote or referendum on the initiated measure will follow). These devices were adopted in the U.S. under the leadership of groups hostile to machine rule, distrustful of legislatures and with a deep faith in democracy. The belief was that by granting the people a means to overrule legislative action and to initiate popular votes on legislation, abuses at the time characteristic of state legislatures might be prevented. Conservative groups were hostile to the adoption of the institution of direct legislation. The chief resort to direct legislation was in the western states, principally in California and Oregon. It did not, however, fulfill the hopes of its advocates or the fears of its opponents. In practice the referendum is used by groups that consider themselves aggrieved by an action of the legislature and feel that they might persuade a majority of the electorate to support them in their demand that the law not go into effect. The initiative tends to be used by groups which have been unable to induce the legislature to enact a desired law. The initiative and referendum proved much less important than the obligatory referendum in bringing issues to the voters. In the legislative process as a whole the initiative and referendum are comparatively unimportant insofar as the volume of legislation directly affected is concerned. The devices may be regarded, in the words of Woodrow Wilson, as a "gun behind the door" to be used when abuses arise in the legislative body. (*See* also RECALL.)

European Countries.—Formal adherence to democratic doctrines in drafting new constitutions in various European countries after World War I led to frequent provision for use of the initiative and referendum. Thus Germany's Weimar constitution of 1919 made generous provision for referenda in certain contingencies, although in fact they were little employed. The same was true of Austria. Less enthusiasm for direct democracy was felt by constitution makers after World War II, but some use of the referendum was provided for. In France the constitution originally proposed for the French republic was rejected by refer-

endum in 1946 and its successor accepted five months later. The constitution later adopted required that any amendment must be submitted to the people unless it has obtained a two-thirds majority of the lower house of the French *parlement* or a three-fifths majority of both houses. In Italy the post-World War II constitution provided that 50,000 electors may present a proposal to the legislature, and, if 500,000 voters or five regional councils request it, a referendum must be held on the question of abrogating a law. Provision was also made for using the referendum as part of the amending process. (V. O. K.; H. G. N.; X.)

REFLECTION. When waves of any kind traveling in one medium arrive at another in which their velocity is different, part of their energy is, in general, turned back into the first medium. This is termed reflection. If the surface of separation is smooth, *i.e.*, if the irregularities in it are small compared with the wave length of the incident disturbance, the reflection is regular; if the surface is rough each facet reflects the rays incident upon it in accordance with the laws of regular reflection (*see* OPTICS) and the reflection, as a whole, is irregular or diffuse. Consider, for example, the reflection of light at smooth and ruffled water surfaces. From the ruffled surface rays enter the eye after reflection from suitably inclined facets distributed over a wide area on the surface and a diffuse band of light is seen, while from the smooth surface only those rays reflected at the requisite angle from a small area on the surface can reach the eye. In the first case the optical system of the eye focuses the water surface on the retina just as it does all other rough surfaces. In the latter the rays appear to come from a laterally inverted replica of the luminous source situated as far below the surface as the source itself is above, and it is this image which is then focused on the retina. The diffusion of light by matt surfaces in general is an example of the same phenomenon differing only in the number and size of the facets which scatter the light. Echoes and reverberations are caused by the reflection of sound (*see* SOUND: *Reflection and Refraction of Sound*) and the fading of wireless signals (in part) by variations in the conditions under which the electromagnetic waves are reflected by the Heaviside layer in the upper atmosphere. *See* RADIO: *Factors Affecting Radio Performance;* MIRROR; *see* also references under "Reflection" in the Index.

REFLEX. Reflex actions consist of comparatively simple segments of behaviour in which the reactions usually occur as direct and immediate responses to particular stimuli uniquely correlated with them. Reflex actions have a widespread occurrence among complex animals. Examples of reflex activities and their neurological mechanisms are given in such articles as ANIMAL BEHAVIOUR: *Animal Behaviour Patterns;* PSYCHOGALVANIC REFLEX; SPINAL CORD; VISION: *Accommodation.*

Conditioned reflexes are built-up adjustments to particular internal or external stimuli. Such conditioning processes were popularized by I. P. Pavlov (*q.v.*) and his co-workers. Pavlov, while investigating digestion, incidentally discovered that salivation occurred in dogs not only when food or acid was placed in the mouth, but also when a bell previously paired with food was sounded. What makes this a typical conditioned interaction is the observable building up of coordinate stimulus and response functions in a unique system (*see* CONDITIONING).

Unconditioned reflexes are exemplified by the reflex tests of the physician. When the neurologist elicits the knee jerk with his hammer stroke or the pupil-closing reflex by directing light to the eye, he is attempting to ascertain whether the organism's biological mechanisms are working properly. For this reason the stimuli may be regarded as simple energy releasers.

Development of Reflex Theory.—The notion of reflex action originally developed in a philosophical rather than scientific atmosphere. For example, René Descartes, who first elaborated the notion of reflex action, did so to distinguish between the automatic action of soulless animals and the voluntary and rational behaviour of human beings. As anatomy and physiology developed in the early 19th century, interest became centred on anatomical and physiological processes of behaviour mechanisms. Although notions of psychic or mental processes were not given up, both biologists and psychologists sought for precise biological locations of "centres" for the production and control of actions. Actions involving mentality or consciousness were regarded as requiring brain centres, while reflex or mechanical actions were presumed to operate on the basis of isolated neural arcs located on various spinal cord levels.

Toward the end of the 19th century and the beginning of the 20th, however, the idea that animals act in parts gave way somewhat to the organismic notion that they act as units and that, therefore, the brain plays a significant part in all actions, including reflexes. In 1906 C. S. Sherrington published researches demonstrating that reflexes are very different from the traditional isolated arcs they were thought to be. Sherrington declared that the familiar diagrams of localized biological reflexes were fictitious and insisted that they must be regarded as integrated actions of the total organism, even though they are simpler than actions classified as voluntary or rational. He also suggested that the stimuli for reflex actions were not simple energy releasers but definite environmental conditions to which the organism adjusted.

With the spread of evolutionary doctrine in the 20th century, reflex theory developed rapidly. The oversimplified notions of isolated neural mechanisms, and even the organismic concept, gave way in great part to the facts of embryological development and ecological adjustment. Important here was the work of C. J. Herrick, C. M. Child, and G. E. Coghill, who showed that even simple reflexes are specialized environmental adaptations developed from original mass behaviours. The capstone of biological progress was the enlargement of the notion of reflexes to include ecologically based behaviour conditioned not only to one substitute object but to several.

Current reflex theory, then, envisages all animal behaviour, and not only reflexes, as continuous ecological evolutions. This does not in any way minimize the importance of the separate cells, tissues, and organs with their normal or pathological participation in adjustments or maladjustments to environmental circumstances. The great importance of this achievement is that both biologists and psychologists are now able to describe all varieties of behaviour, from the simplest to the most complex, without invoking any vitalistic or psychic principles.

Reflexes and Psychological Theory.—Because of the close interrelationship of psychology and biology, the development of reflex theory exerted a great influence on psychological thinking. Especially those psychologists striving for a naturalistic evolution of their science followed the development of reflex notions and were so deeply impressed with the conditioned reflex as model that reflexology became assimilated to psychology. Early behaviourists, such as Pavlov, Karl Lashley, and others, hoped to trace conditioned reflex arcs through the cortex. Evidence for brain-mediated reflexes is presented in BRAIN: *Physiology of the Brain.*

Later behaviourists (E. R. Guthrie, Clark Hull, E. C. Tolman, B. F. Skinner) stressed the stimulus objects and stimulating circumstances. Conditioning became synonymous with learning. In various theories they proposed principles (contiguity of response and stimulus, the manner of stimulus reinforcement, and the effect of stimulation in reducing organic needs) to explain psychological actions (*see* LEARNING; BEHAVIOURISM). *See* also references under "Reflex" in the Index.

REFORMATION, the religious revolution which took place in the Western Church in the 16th century. It broke up medieval Christendom, giving rise to new Protestant churches and to a reformed Catholicism. The object of the Reformers was to secure amendment of errors and abuses in the medieval church, which they claimed to submit to the judgment of Holy Scripture and to the usages of the early church. Beginning as a religious movement, the revolution speedily became involved in political, social and economic pressures. As in all revolutions, there were important elements of continuity, but there was enough abrupt change, discontinuity and explosion to make the Reformation a

turning point in Christian and European history.

VII. Assessment of Fundamental Issues

I. THE MEDIEVAL WESTERN CHURCH

Behind the façade of one western Christendom, with the pope as the spiritual head and the Holy Roman emperor as the secular arm, there had long been tension and indeed division. Heresies lingered as underground movements, while in Bohemia there had been schism and secession on a national scale (*see* HUSSITES). The unity of the empire was sapped by growing national self-consciousness and interests; in Germany political and constitutional divisions impaired the political and military effectiveness of the emperor. Despite attempted constitutional amendments under the emperor Maximilian, the very success of his policy of extending power through dynastic marriages made the government of the empire in the 16th century an almost insupportable task for his successors and prevented any consistent and coherent policies at a time when swift action was demanded. The intricate and conflicting diplomatic interests of pope, emperor and the king of France led to division and to constant war, while the decline of the crusading ideal marked the weakened opposition to the Turk hammering at the gate.

1. The Papacy.—"The Curia at the Renaissance showed a degree of secularization which the early Church would surely have denounced as anti-Christian" (J. Lortz, *Die Reformation in Deutschland*, 1939). In the 11th century St. Peter Damian had protested to Gregory VII against the tendency to pursue spiritual ends by doubtful political means. In succeeding centuries saints such as Bernard of Clairvaux, Hildegard of Bingen and Teresa of Avila, added sharp voices in similar protest. Complaints against this perversion of the gospel in terms of power politics were by no means confined to the soured polemic of the Spiritual Franciscans. The long struggle between pope and emperor, however valiantly the spiritual power championed the "crown rights of Jesus Christ in his church," deepened the political preoccupation, aggravated by the Avignon crisis and the scandal of the Great Schism (1378–1417). Thus the papacy by the end of the 15th century was committed to a network of vested interests, involving diplomatic and military adventures, as well as a whole jungle of administration and law in which was embedded an ugly element of chicanery and graft. Leo X might be a cultured patron of the arts, Julius II a more imposing politician than the bellicose ruffian depicted by Erasmus, Adrian VI a holy man, but at no point in the early 16th century had a spiritual leader arisen who could inaugurate a moral and religious renewal of the whole church.

BY COURTESY OF LUTHERHALLE, REFORMATIONSGESCHICHTLICHES MUSEUM, WITTENBERG

SATIRICAL BROADSHEET SHOWING JOHANN TETZEL AND THE INDULGENCES BROUGHT FROM THE POPE (LEO X. INSET) FOR SALE IN GERMANY

It was a legacy of the conciliar movement that the pope, who had barely escaped being dominated by the church machine, was fearful of a reforming council to which he must surrender initiative or lose control to the emperor, the curia or the episcopate (*see* COUNCIL). The curia itself had long been the arena of competing Italian noble families, among whom nepotism was a recognized weapon of power. The great international civil service, that fine achievement of the Avignon popes especially, had run to seed, becoming, like Charles Dickens' "Circumlocution Office" (in *Little Dorrit*), the prey of overorganization, inefficiency and venality in an age which knew too much, in any case, of "the law's delays, the insolence of office." Finance and law had come to play too big a role at the heart of the Christian world. Vast sums of money, huge debts in a great business extending from one end of Christendom to another had to be handled by bankers such as the Fuggers of Augsburg, and these financial preoccupations affected moral and spiritual issues such as those involved in the sale of indulgences. The church had come to possess immense wealth and in some countries owned an alarming proportion of the land. Much of this wealth was necessarily drained off by the papacy and the higher clergy.

The pastoral machinery of the church was concurrently distracted from the cure of souls as the higher clergy provided the administrators, councilors and officials not only of the church but of the secular kingdoms, despite the fact that a growing lay administrative class was an important fact in the pre-Reformation scene. Pluralism and nonresidence aggravated the shortcomings of the pastoral machine, while a too numerous class of poor and unlettered clergy coped badly with the duties often neglected by their superiors. The long, notorious abuse of excommunication for unworthy or trivial ends, and the grasping litigiousness of the spiritual courts, had brought ecclesiastical discipline into ill repute.

The religious orders were often relaxed and worldly, housing many who lacked any true vocation for the evangelical perfection they no longer strenuously sought. If there was not as much

gross immorality as the moralists suggest, there was more than enough. At the end of the middle ages, the venality of the mendicant orders had become a byword. The result was that this overclericalized Christian world gave rise to widespread anticlericalism in the later middle ages, among scholars and merchants and the common people, an antagonism which found expression in the writings of satirists from the time of Langland and Chaucer to Erasmus and More, which found vehement expression in the *Epistolae obscurorum virorum* ("Letters of the Obscurantists") of the Rhenish humanists (*see* REUCHLIN, JOHANN) and showed its public virulence in the crisis of Hunne's case in London, 1514–15.

It is more difficult to generalize about the religion and faith of common men. But there is plenty of evidence of widespread fear and superstition. Evidence, too, of an externalizing of religion, an emphasis on outward works and technical ecclesiastical duties, which, taken together with a doctrine of merit not clearly expounded, attracted the acid criticism of such catholic humanists as Sir Thomas More, John Colet, Desiderius Erasmus (*qq.v.*), Konrad Peutinger and Willibald Pirckheimer. The communion of saints, the sacred commerce between heaven and earth, became itself a means of clerical exploitation, and the literature of Catholic humanism bears witness to the superstitions and abuses connected with it and with the doctrine of purgatory. Witch-hunting, gross superstition, fanaticism belong as much to the social background as to the church, for the veneer of Christian civilization had always been thin in some areas of medieval Europe, but recurrent apocalyptic panic and sombre revivalism is a part of the late medieval background which is not to be ignored.

There remained, despite all this, the unfailing offices of the liturgy of the church and of its sacramental system. But it seems evident that the liturgy of the church had become overcomplicated, and the eventual reforms of the Council of Trent (*q.v.*; 1545–63) in the matter of preaching and pastoral care are the best evidence of the neglect of these things in the preceding 50 years. There is no need to overdarken this picture, for which chapter and verse could be given from Catholic writers. It was Cardinal Reginald Pole who told the second session of the Council of Trent (Jan. 1546), "We ourselves are largely responsible for the misfortune that has occurred . . . for the rise of heresy, the collapse of Christian morality, because we have failed to cultivate the field that was entrusted to us. We are like salt that has lost its savour" (H. Jedin, *History of the Council of Trent,* vol. ii, p. 26, translated by E. Graf; Thomas Nelson & Sons Ltd., 1961).

Nonetheless, it would be foolish to underestimate the positive good achieved by a creaking and groaning ecclesiastical machine. Though abuses clustered round each point of the sacramental system where it touched the cure of souls, there are abundant signs that these things did not prevent the work of divine grace.

Indeed, by the second decade of the 16th century, it was arguable that the worst was past. Not again would the papacy become what it had been as a tool of the Borgias. There had been energetic attempts to find a platform of reform in the fifth Lateran council (1512–17) and in the even more successful and reforming movement of Cardinal Francisco Jiménez de Cisneros in Spain. Though the 14th-century revival of inward religion, the *devotio moderna,* had become an ascetic and sometimes obscurantist pietism, it still inspired the valiant attempt of Jean Standonck to reform Parisian religious houses with its aid. A conflation of the *devotio moderna* with German mysticism had much to do with the reforming zeal of the German Augustinian Johann von Staupitz, who attempted a reform of his order in Germany. In fact, in this period there were many new orders, new brotherhoods and religious sodalities and, among the older orders, attempts by Observants to reform in line with the authentic intentions of their original rule. The widespread institution of preacherships in south German cities is a sign that some spiritual and secular authorities were sensitive to the need of the church at this point. The invention of printing *c.* 1440 made available a whole spate of edifying and catechetical literature of astonishing richness and diversity at the beginning of the 16th century. (*See* also PAPACY.)

2. Reformers Before the Reformation.—The older Protestant historians were wont to single out those whom they regarded as the true precursors of the Reformation, too often reading back 19th-century "principles" (*e.g.,* toleration and the right of private judgment) into the 16th century. It is easy to pick out isolated sentences in commentaries by Wycliffe, Huss, Colet, Wessel Gansfort or Lefèvre d'Étaples which suggest that they anticipated Luther's doctrine, and to forget the even more important elements they shared with their Catholic contemporaries. Of these men, perhaps John Wycliffe (*q.v.*) has most claim to be thought of as a precursor of the Reformation. In his appeal to the supreme authority of Holy Scripture there is evident, more than in the heavily Aristotelian writings of Marsilius of Padua and William Ockham, a directly biblical antidote to the canonist doctrine of the papal plenitude of power. Modern study has stressed his intricate scholasticism, how much he had in common with other students of St. Augustine in that age, and yet unlike them, but like the Reformers, he set off some kind of ecclesiastical explosion. That it was isolated, muffled, is perhaps because Wycliffe lacked two of the vital agents of the Reformation: the invention of printing and the new tools and methods of the humanists which provided a microphone and megaphone for the Reformers.

3. Humanism and the Reformation.—This is not the place to define humanism, to question whether there was in fact a Renaissance or to discuss the merits of the humanists as scholars (*see* RENAISSANCE). At least of negative importance is the fact that throughout the century before the Reformation a number of critical satirical writings had provided an acid ferment within the church, a focus for anticlerical sentiment. More positively, there was the advent of new tools and a new critical method. The return to classical antiquity, the search for better texts, was illustrated in the new edition of Aristotle which Jacques Lefèvre d'Étaples (*q.v.*) provided for his Paris students. It was when applied to sacred letters that the new technique became of catastrophic importance. There was, first, the revived study of the sacred languages, Hebrew, Greek and a renovated Latin. The lack of philological tools in the way of grammars and dictionaries limited the scope and value of humanist biblical scholarship but not the immediate effect on contemporaries. There was a new insistence on the importance of securing the best possible text, based on the best manuscript authorities, and these were to be interpreted not uncritically in terms of traditional authority but in the exact, philological, historical context.

Landmarks in this biblical humanism were the Complutensian Polyglot Bible, the work of a brilliant team of Spanish scholars at Alcalá, and the immense tour de force of Erasmus' edition of the New Testament in the original Greek (1516; revised edition, 1519), the prefaces of which were manifestoes of the new method. What had been to Lorenzo Valla or to Johann Reuchlin philological principles became of theological importance for Erasmus. The theology of Nicholas of Cusa, the thinkers of the Florentine academy, Marsilio Ficino and Pico della Mirandola had suggested a broader approach to questions of truth than had scholastic theology, and in Erasmus this became the simple, practical study of the "philosophy of Christ," the way of life set out in the Gospels and in the Epistles of St. Paul. He exhorted men to the direct study of the Scriptures, which he hoped might be made available for wayfaring men and women in their own tongue.

4. Indulgence Controversy.—The occasion of the Reformation must be clearly distinguished from the deep, underlying causes. Martin Luther (*q.v.*) claimed that, while others before him had attacked the papal morals, he had gone to the theological roots of the matter, the perversion of the doctrine of grace, the externalizing of the sacrament of penance and the consequent ensnaring of consciences in a legalism contrary to the spirit of the gospel. But the occasion was practical enough, the sale of indulgences (*see* INDULGENCE). These offered spiritual privileges on papal authority, including the commutation for money of those acts of satisfaction which formed part of the sacrament of penance. About their theory, and particularly their application to the dead, there was some of that uncertainty which J. Lortz has noted as a defect of the Roman Church before the Council of Trent, and theologians argued and moralists protested about their use and

abuse. For while the wording of the indulgence excluded the notion that forgiveness might be bought, or was available to the impenitent, the language used by some sellers of indulgences was not so discreet.

The immediate cause of scandal in Germany in 1517 was the issue of an indulgence which was to pay for the rebuilding of St. Peter's, Rome. But by a secret agreement of which most Germans, including Luther, were unaware, half the proceeds of the German sales were to be diverted to meet the huge debt owed to the Fuggers by the archbishop and elector Albert of Mainz, a debt incurred by his inability to pay the fees on his accumulation of high benefices. Such a prince could not afford to be squeamish about the methods and language used by his agents, and the commissary in Germany, the Dominican Johann Tetzel, spoke in terms which were extravagant and scandalous. Luther was outraged when he learned of this from his own penitents who brandished their pardons before him. The sale of this indulgence was forbidden in Wittenberg by the elector Frederick III (*q.v.*) the Wise, who preferred that the faithful should make their offerings at his own great collection of relics, exposed on high days in the castle church. It was therefore a fateful moment when on the eve of All Saints' day Luther nailed to the door of the church 95 theses concerning indulgences, offering to dispute them "for the sake of eliciting the truth." He had on the same day written to the archbishop and to his ordinary, the bishop of Brandenburg, protesting against the language used in the handbook of instructions for indulgence sellers. Yet the theses were not extreme, and about many of them Luther himself had not made up his mind. He had preached against indulgences some months before and, though this was a public protest, it was in no sense a deliberate schismatic and revolutionary act. But here the invention of printing intervened. What might have been confined to a few copies circulating among neighbours was turned overnight into a manifesto which swiftly circulated through Germany, attracting ever-widening publicity, turning a protest about a genuine scandal into the greatest crisis in the history of the Western Church.

II. LUTHER'S REVOLT, 1517–21

1. Luther and Early Supporters.—Martin Luther, professor of theology in the University of Wittenberg, was at this time a theologian of growing rèpute, of some importance in the Augustinian order. He was alarmed to find that his honest protest was interpreted in terms of proud defiance and to learn that steps were being taken to secure his silence. Faced with a demand of unconditional recantation and complete submission to papal authority, Luther was forced to reconsider his whole attitude to the authority of the pope, of councils and of Holy Scripture. Two events especially stimulated him to further protest, his interview with Cardinal Cajetan (*q.v.*) at Augsburg, 1518, and his debate with Johann Eck (*q.v.*) at Leipzig in the following year. In June 1520 the papal bull *Exsurge domine* condemned 41 propositions attributed to Luther. (His excommunication followed in 1521.) Luther retorted in a fluent series of fiery writings, chief among which were his two manifestoes of 1520, *An den christlichen Adel deutscher Nation* ("An Appeal to the Christian Nobility of the German Nation") and *De captivitate Babylonica ecclesiae praeludium* ("A Prelude Concerning the Babylonish Captivity of the Church"). The first, in lucid German, summed up the rising tide of national German grievance against the exactions and tyrannies of Rome. The second, in Latin, made an even more revolutionary attack on the hierarchy and the sacramental system. By now it had become plain that there were great forces on Luther's side and that his teaching found an echo in important classes of the community, not least the knights, the peasants and the merchant burghers of the towns. The scholars were divided by the vehemence of Luther's protest, but among them too, in many lands, he won at least qualified approval, and from some wholehearted support.

With dramatic defiance which caught the imagination of Europe, Luther appeared before the young emperor, Charles V, at the imperial diet in Worms, April 1521. He refused to recant or disavow his writings, on the ground that his conscience must obey

BY COURTESY OF THE TOLEDO MUSEUM OF ART, GIFT OF EDWARD DRUMMOND LIBBEY

"MARTIN LUTHER AND HIS FRIENDS," DETAIL OF A PAINTING FROM THE STUDIO OF LUCAS CRANACH THE ELDER, IN THE TOLEDO MUSEUM OF ART, TOLEDO, O. IN THE CENTRE, THE ELECTOR FREDERICK III OF SAXONY, SURROUNDED BY (LEFT TO RIGHT) LUTHER, SPALATIN, OSIANDER, BUGENHAGEN, AND MELANCHTHON

the Word of God. Under a safe conduct he was allowed to go, but the edict of Worms, passed by a rump diet after his departure, outlawed him, thus inhibiting his movements for the rest of his days and forcing caution upon the elector Frederick, his patron. The result was Luther's friendly captivity in the castle of the Wartburg. There he continued to pen influential writings, most notable of all his translation of the German Bible, a work which was deeply to influence the life and religion of Germany.

Now the far-reaching implications of the new teaching had to be faced. Theological changes, such as the restoration of communion in both kinds to the laity, the abolition of private Masses, the denunciation of celibacy of clergy and of monastic vows, had immense financial, juridical and social consequences. In Wittenberg itself some of Luther's colleagues, notably Andreas von Karlstadt (*q.v.*), wished to step up the pace of reform and go farther and faster than Luther or his gifted young colleague, Philipp Melanchthon (*q.v.*), were prepared to go. The radical party demanded the abolition of religious pictures and images and institution of a vernacular, simplified liturgy. They pushed through reforms on these lines early in 1522, when the magistracy passed the *Ordnung der Stadt Wittenberg* ("Ordinance of the City of Wittenberg"), the forerunner of innumerable civic ordinances elsewhere. At this time the imperial government at Nürnberg issued a sharp warning against any innovations involving social disorder, so that the elector Frederick and his adviser Georg Spalatin (*q.v.*) were more than ever afraid of change. In March 1522 the situation was getting out of hand, and it was redressed only by the return of Luther himself, under whose forceful preaching order was restored and a number of innovations canceled. One result was to slow down change in Wittenberg, and not until 1526 did Luther provide a vernacular liturgy (*Deutsche Messe*). Karlstadt retired to the village of Orlamünde on the Saale, where he converted his parishioners to his own brand of mystic puritanism and where he remained a troublemaker. In other parts of Thuringia, too, there was a radical ferment at work. The fiery Jakob Strauss in Eise-

nach inveighed against usury and tithes. More influential was the preacher in Allstedt, Thomas Müntzer (*q.v.*). In him Lutheran notions jostled alongside medieval mysticism and Hussite anticlericalism. Having failed to win the inhabitants of Prague to his new order, he returned to dominate the little town of Allstedt where his turbulent preaching and liturgical experiments became a growing scandal. He was expelled from the town in the summer of 1524 and sought new pastures in south Germany where social revolution was imminent.

2. Peasant War.—In the summer of 1524 a series of sporadic, ill-co-ordinated risings began in the Black forest, extending rapidly through Swabia and the Rhineland. The rebel demands varied, sometimes based on Catholic doctrine, elsewhere appealing to the "righteousness" advocated by Luther and Zwingli. In the main the rebels were not so much concerned with abstract justice as with the redress of specific grievances, forest and game laws, tithes and the like.

With few leaders of military ability and no planned commissariat, the peasants roamed destructively about the countryside, burning and pillaging, terrorizing the inhabitants and conscripting small towns and local gentry into their ranks. At first, in the absence of organized and armed opposition, they gained immense success, but they rarely survived a set battle. Thus the Thuringian peasants under Thomas Müntzer in May 1525 were overthrown at Frankenhausen by a coalition of the forces of the evangelical prince Philip of Hesse and the Catholic duke George of Saxony. After the rout and its bloody sequel, Müntzer was taken, tortured and, after recantation, executed. Modern Soviet historians see in him the real hero of the "People's Reformation." Yet his incitement was not to class war but to anticlericalism, and his scanty teaching about social equality is entirely subordinate in his apocalyptic theology. Many of his disillusioned disciples and followers joined the radical Anabaptist movement (*see* ANABAPTISTS).

3. Luther and German Protestantism (1525–46).—By 1525 Luther no longer dominated the already many-sided Reformation, though he remained the leader of the growingly coherent Lutheran Church. He was much criticized for his attitude during the Peasant War. Though he had for long warned civil rulers against the dangerous consequences of radical preaching in Saxony, and though he gave moderate counsel to both sides at the beginning of the rebellion, more attention was attracted by his hysterical broadsheet, *Wider die räuberischen und mörderischen Rotten der Bauern* ("Against the Murdering, Thieving Hordes of Peasants"), written at the height of rebel success but published after their collapse during bloody reprisals by the young princes. Though neither before or after 1525 could Luther be accused of undue subservience before authority, many who had rather loosely considered themselves his followers turned in disillusion to the new Anabaptists. Yet Lutheranism did not cease to be a popular movement; it continued to gain ground among all classes in the German towns and countryside. After the death of Frederick III the Wise (1525), Luther's old patron though never his disciple, the two succeeding electors, John and John Frederick, were Lutheran princes in a new sense. It was at this time, too, that Luther married a former nun, Katherine von Bora, a common-sense match which turned out marvelously well, and as the former Augustinian monastery in Wittenberg became a Protestant manse the new domesticities mark perhaps another stage in the circumscription of Luther as a Saxon Reformer.

Luther's *De servo arbitrio* (1525), in reply to the attack of Erasmus' *De libero arbitrio* (1524), was a powerful treatise on the doctrine of free will, which marks the alienation from his cause of an element in humanism which had begun by treating him with sympathy but which had been more and more alienated by the violence of his language, the boldness of his repudiation of traditional churchmanship and the failure of his reformation to produce more evident moral fruits. His treatise, also in this year, *Wider die himmlischen Propheten* ("Against the Heavenly Prophets"), was a profound exposition of the difference between his theology and that of the radicals, Karlstadt and Müntzer.

Luther's liturgical order, the *Deutsche Messe* (1526), and his catechisms (1529) became the prototype for the innumerable Lutheran church orders of the next half-century. His children's catechism, especially, was a work of great beauty. His translation of the Bible from the original languages into German, which was finally published in complete form in 1534, went into many editions, some of them finely illustrated, and made deep impress on the life of the German people. He encouraged his friends to write, and himself composed more than a score of fine hymns (*see* also GERMAN LITERATURE: *The Reformation;* BIBLE, TRANSLATIONS OF; HYMN).

Luther conducted a great correspondence, both in and outside Germany, dealing with problems of conscience, pastoral care and church organization. He continued to give courses of lectures, attended by students who went out into all parts of Europe as his disciples, spreading the Lutheran Reformation. In the work of Reformation he was more and more aided by his colleague Philipp Melanchthon, to whose irenical spirit he entrusted more and more ecclesiastical negotiations. Though Luther's own educational writings are important and fruitful, Melanchthon's humanistic learning and his programs and textbooks earned him the title "preceptor of Germany." Melanchthon was responsible for drafting the Augsburg Confession (*q.v.;* 1530), the foundation document of the Lutheran Church as well as of the political Schmalkaldic league. In 1527–28 a commission of lawyers and theologians began a visitation of Saxony, and this became a prototype of Lutheran administration. The Reformers had now to fill the vacuum left by canon law and Catholic discipline, and they developed the important consistorial court to deal with administrative and disciplinary problems, especially concerning marriage.

Luther himself distrusted secular influence in church affairs, and while he lived there was not much cause for complaint on this score. After his death, the way was open for more and more authority to concentrate in the hands of the secular ruler. One by one the great German cities turned to the Reformation, though after 1526 there was usually a tension between the Lutheran and Reformed types. Luther's colleague, Johann Bugenhagen, became the organizer of Lutheranism in north Germany and in Denmark. By 1529 the Lutheran cause was represented in the imperial diet by a group of princes, including the elector of Saxony, the landgrave of Hesse, the margrave of Brandenburg and the prince of Anhalt. The restoration of the Lutheran duke Ulrich to Württemberg in 1534 and, even more, the accession of ducal Saxony on the death of Luther's ancient foe, Duke George, in 1539, were signal advances. Nonetheless, the last years of Luther's life were years of growing Catholic resurgence: the long-threatened papal council became a reality, and there was a political and military coalition of Catholic powers. His aging body racked with illness, Luther continued to preach and teach and to write until his death in Feb. 1546.

III. GERMAN AND SWISS REFORMERS

1. The Emperor Charles V and the German Princes.—About the devotion of Charles V to the Catholic faith, and his hatred of the Reformers and all their works, there was never any doubt. But he had a layman's distrust of theological niceties and was prepared to make concessions for the sake of restoring unity. Circumstances forced realism upon him, and in times of emergency he was vulnerable to the advice of counselors more sympathetic than himself to the new teaching. The many preoccupations of his vast sprawling empire, in Spain, the Netherlands, Germany, Austria and Hungary, the constant menace of the Turkish invasion, his own diplomatic and military entanglement in incessant quarrels with popes and kings of France—all these intervened again and again to keep him away from Germany or to prevent him from implementing the edict of Worms against Luther and his teachings. The German princes played for their own political hands, and it was not only those who favoured the Reformers who insisted that the grievances of Germany against Roman exactions must be dealt with by a free council on German soil. In 1526 the Turks won a great victory at Mohacs. That year, under the menace of Turkish invasion, a recess of the imperial diet at Speyer left each ruler free to act as he should answer "to God and the emperor." By 1529 the emperor could take a stronger line, and the Catholic

majority in the diet withdrew the earlier concessions, provoking the historic *Protestation* of the minority of evangelical princes and of 14 imperial cities, which earned them the title "Protestants."

2. Philip of Hesse.—The most energetic and politically minded of the Protestant princes was the landgrave Philip (*q.v.*) of Hesse. In Hesse the Reformation developed its own characteristics, for he enlisted the aid, first of the French Reformer Franz Lambert (*q.v.*) of Avignon, and then of Martin Bucer (*q.v.*), from Strasbourg. Reforms were canvassed at a synod at Hamburg in 1526 and promulgated at Ziegenhain in 1538. Hesse was notable for a conciliatory policy toward the Anabaptists which won many back to the church. In the vulnerable Palatinate, Philip knew the need for political alliance, and in the hope of restoring the broken eucharistic front invited Swiss and German theologians to a colloquy in his palace at Marburg in Oct. 1529, a conference which foundered on the refusal of Luther or Huldreich Zwingli to compromise their convictions (*see* MARBURG, COLLOQUY OF). Philip was one of the chief members of the Schmalkaldic league (Feb. 1531) formed to offset the coalition of Catholic princes. Though a zealous Protestant, his inability to control his passions led to the scandal of his bigamy (1540). Bucer, Melanchthon and Luther—in that order—were reluctantly driven to acquiesce in the grant of a secret dispensation for bigamy, which when it became public rendered the prince guilty of a breach of the law of the empire.

In 1530 the emperor attended in person the diet at Augsburg. While Luther, as an outlaw, had to fidget in Coburg castle, the Protestant cause was represented by Melanchthon, who drew up the Augsburg Confession for the occasion. Encouraged by hopes of reconciliation with the Catholic side, Melanchthon was prepared to draw away from the Swiss Reformers and heartily to damn the Anabaptists. Bucer presented a more radical document, the *Confessio Tetrapolitana*, on behalf of Strasbourg, Constance, Lindau and Memmingen. The Catholics replied with a vast catena of Protestant heresies, prepared by Johann Eck, with a theological *Confutatio* and with an imperial ultimatum to the Protestant princes. Nonetheless, the strength of the Protestant alliance and the need for help against the Turks forced the emperor once again to postpone action and to call a truce at Nürnberg in 1532 which gave the Reformers a critical interval in which to consolidate their gains and a valuable breathing space. Moderates on both sides of the great divide still hoped for reconciliation, and a series of conferences were held, led by Melanchthon and Bucer on the one hand and a number of Catholic theologians, some of them influenced by Erasmus, on the other. These were held at Hagenau and Regensburg (1539–41) but eventually broke down on the doctrine of the Mass.

In 1541 Philip of Hesse temporarily abandoned his allies in the Schmalkaldic league and joined the emperor's League of Nürnberg, thus seriously weakening the Protestant front. By 1546 Charles V was in a strong enough position to concentrate on disposing of the Schmalkaldic league, and with the aid of the renegade Maurice of Saxony, himself a Protestant, surprised, defeated and captured the elector, John Frederick, and Philip of Hesse at Mühlberg in 1547. In 1548 at Augsburg the victorious emperor dictated the terms of an imperial "Interim" which, though something of a compromise, resulted in the exile for conscience's sake of Martin Bucer and some hundreds of Protestant pastors. But once again the military intervention of the king of France ruined Charles V's ambitious plots, and in the next years Charles was forced to hand over German affairs to the archduke Ferdinand, abdicated his vast dominions and retired to a monastery in Spain. The peace of Augsburg (1555) recognized the stalemate between two groups of powers neither of which could immediately overthrow the other, gave recognition to the Protestants and acknowledged their legal right to secularized church property in their lands. The political divisions of Germany were now further confounded by the addition of the religious barrier, since the principle that subjects must adopt the religion of their prince (*cuius regio, eius religio*) ended the myth of German unity and substituted religious territorialism for the concept of one Holy Roman empire of the German nation, thus permanently tying religious and political affairs.

3. The Reformation in Switzerland and South Germany.—By 1525 other patterns of Reformation were emerging, distinct in origin and ethos from that of Luther, drawing on other spiritual influences from the late middle ages, such as the *devotio moderna* and German mysticism, and developing an austere Puritanism which was critical of the "this worldliness" with which Luther opposed Catholic asceticism. Now this pattern found a more moderate setting in the Reformation in the cities of Switzerland and south Germany, in the leadership of Huldreich Zwingli (*q.v.*), Bucer and John Calvin (*q.v.*), who were the founding fathers of the emerging Reformed as distinct from the Lutheran Protestant tradition. In these oligarchic communities corporate self-consciousness was intensified by long struggle for liberties against feudal lords and by the internal movement within the complex guild structures. Here, too, the godly magistracy offered a swift and effective instrument for carrying through public reform. The situation varied very much from city to city. The presence of a bishop (Basel), a cathedral or collegiate church (Augsburg), an abbey (Sankt Gallen) or a university (Basel) slowed up the pace of reform, which was accelerated by the presence of an eminent Reformer (Zürich, Strasbourg), usually clerical but sometimes (Sankt Gallen) lay. No doubt economic interests counted, and the presence of the great Catholic banking families of Fugger and Welser held up reform in Augsburg at a time when Nürnberg had already become Lutheran.

But the story cannot be explained in terms of vested interest or of a class struggle between patricians, merchants and craft guilds. For though these considerations explain some of the facts,

they do not account for ways in which Reformers (*e.g.*, goldsmiths) behaved against their own economic self-interest, and though in Zürich and Basel the impetus came from the craft guilds, in Constance and in Bern the patrician element was important; indeed, in Constance the main opposition to Reform came from the proletarian fishermen's guild.

Ernst Troeltsch and Max Weber, and a famous essay by R. H. Tawney, placed Protestantism in close connection with the rise of capitalism. While Luther's economic theories were medieval and backward-looking, it was asserted, Calvinism, and English Puritanism in consequence, fostered a this-worldly, forward-looking enterprise which in part provoked and certainly accompanied the new social morality of the capitalist system. The theory has been much modified by later research and criticism, and the supposed contrast between Catholic and Protestant social ethic has been shown to be less significant than had been suggested. It is true that the Reformers stressed the duty of men to labour in their calling and emphasized the virtues of thrift and industry (the "gospel of hard work" is prominent in Bucer). The work of W. K. Jordan has emphasized that Protestant religion found expression in new forms of philanthropy, in the relief of sick and poor and care for education, in ways which offset and in part replaced the medieval works of mercy.

4. Zürich and Zwingli.—Huldreich Zwingli from the Alpine

Toggenburg was a patriotic Swiss who after a few years as parish priest was appointed to the Grossmünster (cathedral) in Zürich. There in Jan. 1519 he began a ministry of prophetic preaching, expounding St. Matthew's Gospel from beginning to end and continuing with other biblical books before an audience which included most of the civic leaders, in an exposition always closely related to public affairs. An important instrument for clerical education were the "prophesyings" at which he and his clerical companions expounded the Old Testament, and one fruit of this was the Zürich Bible of 1529, the work of Zwingli and his scholarly colleagues, Conrad Pellicanus, Leo Jud and Bibliander. Though Zwingli plausibly claimed to have rediscovered the Pauline gospel of justification by faith independently of Luther, the Reformation movement in Zürich began with his protests against the Lenten fast in 1522.

The technique of the Zürich Reformation was followed in other cities. An evangelical mandate from the town council gave the new, direct scriptural preaching some kind of footing. A public disputation was held, no longer an academic exercise but rather a deliberate appeal to public opinion and official decision. There followed the promulgation of evangelical ordinances by the magistracy, regulating preaching and worship, abolishing images and the Mass, reorganizing discipline and administration.

This reform by public law was prepared for and accompanied by energetic preaching ministries in the city churches, and Zwingli and Bucer in particular were aware of the dangers of a merely outward Reformation carried through by public law. In the case of Zwingli, this appeal to the magistracy was by no means subservience or expediency but was rooted in his thought of the city as a Christian commonwealth. Zwingli prepared 67 theological articles for the first Zürich disputation (Jan. 29, 1523). His friends assembled with him in the Grossmünster behind Bibles, in Greek, Hebrew and Latin, as a sign that they would accept only Scripture, not church authority, as arbiter. Outmaneuvered, the Catholics put up no sort of fight, and the authorities declared for Zwingli. A further disputation took place in October concerning images and the Mass, but it was not until 1525 that action followed from the magistrates, and Zwingli's drastically simplified communion rite was published and authorized.

By this time a group of Zwingli's more ardent younger men had turned against him, angered by his reluctance to proceed with Reformation more swiftly than the magistrates were prepared to go; they provoked in Zürich a radical rebellion which became the Anabaptist movement. Older historians overstressed Zwingli's rationalism and humanism and overlooked his noble conception of his city as a prophetic community, where church and magistracy could work hand in hand. He prefaced his tracts with the evangelical invitation "Come unto me . . . ," for his conception of a Christian commonwealth made all life, private and public morality included, a sounding board for the gospel. Nonetheless, he was a Swiss patriot and became imbued with Zürich imperialism, evident in his dealings with Sankt Gallen and with Waldshut. Alarmed at the growing menace of Catholic power and the isolation of Zürich, Zwingli strove to build an alliance, the "Christian civic league," with the Protestant cities of Bern and Basel and with Strasbourg from without the Swiss confederation. These adventures into high politics led to the disastrous battle of Cappel against the Catholic cantons (Oct. 1531), in which Zwingli was slain. His young successor, Heinrich Bullinger (*q.v.*), continued the religious and theological program of Zwingli without the disastrous foreign policy, and though Zürich remained an important centre of Reform it no longer dominated the Reformation in the south.

5. Basel and Oecolampadius.—Very different from the hard-headed Zwingli was his friend and colleague, the warmhearted John Oecolampadius (*q.v.*). He was supremely a scholar and a preacher—suited to be the leader in a university city famous for its books and its publishing houses, its rich men furnished with intellectual ability. He was of all the Reformers perhaps the most learned in the Church Fathers, and he was skilled in the Hebrew, Greek and Latin languages. In Basel there were strong Catholic forces rallying round the Münster and its chapter, and the pace of reform was slow. After assisting Erasmus with the launching of his New Testament, Oecolampadius returned to Basel in 1532 as professor of Old Testament. He outgrew an initial dilettantism and took a lead at the disputation at Baden in 1526 against Johann Eck and Johann Faber. In 1528 he attended the disputation at Bern which decided the fate of the Reformation in that city and returned determined to press for a similar success in Basel.

This second disputation took place in the winter of 1528–29, and at Easter, after growing iconoclasm and tumult, great reforming mandates were passed by the magistrates. The cathedral chapter left for the other side of the Rhine, and a number of scholars went with them, including Erasmus. Overwhelmed with grief at the death of Zwingli, Oecolampadius died only a few weeks after him. His work was carried on by Myconius (Oswald Geisshüssler). In Bern, important though it was (in subsequent decades it surpassed Basel and Zürich as a centre of reform), there was no leader of real eminence, and the clerical leader, Berchtold Haller (1492–1536), was less important than the poet-statesman Niklaus Manuel. There, too, Reformation came by civic mandate after the highly successful disputation at Basel in 1528.

6. Strasbourg and Bucer.—Strasbourg was an imperial free city, commercially important but strategically vulnerable, politically and geographically isolated from the Swiss cities. Its Reformation was launched by a group including the cathedral preacher Matthew Zell, the scholar Wolfgang Capito (*q.v.*), the educationalist Johannes Sturm, the statesman Jakob Sturm and above all Martin Bucer. Bucer arrived in Strasbourg, an ex-Dominican on the run, unemployed and penniless, in 1523, but soon dominated the Reformation movement in the city. He developed much of the theology of the young Luther but with his own stresses on election, on the doctrine of the church, on the need for catechetical instruction, on the importance of a doctrine of sanctification and on practical philanthropy. He was much engaged in stimulating liturgical reforms, and it has been said that "for him the Church is built round hymn-singing." Above all, as Margarethe Blaurer (sister of the Reformers Ambrosius and Thomas Blaurer) said, he was "a fanatic for unity" and spent much of his energies in attending ecclesiastical conferences in one country after another.

Although his work centred in Strasbourg, Bucer was called in to assist Reformation in Ulm, Cologne and Hesse. Strasbourg was a city of refuge for radicals and there was a considerable Anabaptist uproar with which Bucer tried to deal firmly but more tolerantly than did the Lutherans or the Swiss. After the promulgation of the Augsburg Interim in 1548 Bucer went into exile in England, where he died in 1551. Although Bucer's position mediated between the Lutherans and the Swiss, he must be regarded as one of the fathers of the Reformed Protestant tradition, though Strasbourg itself, after his departure, became dominantly Lutheran.

See also REFORMED CHURCHES.

IV. ENGLAND

As the territorial princes of divided Germany played the role performed in the cities by the "godly magistrates," so in the politically unified kingdoms of England, Scotland, France and Scandinavia the *jus reformandi* was exercised by the "godly prince."

Much the same conditions prevailed in rather remote England as at the centre of medieval Christendom. There were notable humanists such as Thomas Linacre, William Grocyn, John Colet, John Fisher and Sir Thomas More. The case (1514–15) of Richard Hunne, a London merchant who sued a priest, was countercharged for heresy and found dead in the bishop of London's prison, revealed a ferment of anticlericalism in the capital. Pockets

of sectarian heresy—simple, anticlerical, lay in leadership and roughly labeled "Lollard"—existed throughout the country, even in the north, though most strongly in the Thames valley and in East Anglia (*see* LOLLARDS). Books by Erasmus and Luther were circulating in England after 1520, and though many of these writings, with the biblical commentaries of other Reformers, were proscribed by the authorities, they were sold in secret traffic to undergraduates and doctors at Oxford and Cambridge and in some of the larger monasteries.

At Cambridge a group of scholars favouring reform were in trouble at the end of 1525, eminent among them Thomas Bilney, Hugh Latimer (*q.v.*), Robert Barnes—all eventually burned. In 1526 the exiled William Tyndale produced an English New Testament which was a work of genius. Thus, five years later than in Germany—a significant time gap never really caught up—the Reformation movement was stirring in England, particularly among the scholars, the merchants and the court.

1. Henry VIII.—Henry VIII, gifted and ruthless, was a formidable Renaissance prince. The Wars of the Roses had thinned out the nobility, saving the Reformation in England from its fate in France and Scotland where it became involved in the tussle between nobility and crown. But the fear of renewed civil war over claims to the crown remained a Tudor bogey from the 15th century and was one reason for Henry's anxiety for a male heir. This became for him a case of conscience when there was no son to his marriage with Catherine of Aragon. It called in question the validity of his marriage, as Catherine had been the wife of his deceased brother Arthur, and of the papal dispensation which had made this possible, and, once raised, the question uncovered a whole legal and theological complex of disputable arguments. Reasons of state, therefore, may be fairly added to Henry's passion for Anne Boleyn which led him to seek divorce. The king found there were limits to papal compliance, especially as Catherine was aunt of the emperor Charles V and formidable European sympathies were on her side.

The great cardinal Thomas Wolsey was an early victim of the royal impatience, and the king found a ruthless and compliant servant in Thomas Cromwell, an able administrator, and an archbishop of integrity in Thomas Cranmer, who firmly believed in the authority of the godly prince, which, with Holy Scripture, offset the papal claim to plenitude of power. The clergy were browbeaten into submission under the medieval acts of *praemunire* (*q.v.*). Henry got his divorce and married Anne. The Reformation parliament, summoned in 1529, carried through under royal direction a series of enactments which lopped off one by one the great financial, legal and administrative cables which joined the English state with western Christendom, the English church with the Roman see. An Act of Succession was passed, to which an oath of allegiance was required, and an Act of Supremacy declared Henry to be supreme head of the Church of England, the inheritor of the jurisdiction of the bishop of Rome. Henry showed his ruthless determination by executing John Fisher and Thomas More, and a noble band of obstinate Carthusians. But over the country as a whole the resistance was significantly slight.

The suppression of the monasteries (smaller houses in 1536, larger in 1539) was of major importance in the consolidation of the break with Rome. This was carried through under the oversight of Cromwell as the king's lay vicar-general on the basis of tendentious reports from his commissioners. But though the amount of scandalous immorality in the monasteries may have been exaggerated, a relaxed worldliness was evidently widespread, and most of the religious went back to the world cheerfully accepting their pensions, for the most part unlamented. The spoliation of the shrines and the sale of monastic property brought wealth to a needy and extravagant king, whose military attempts to cut a figure in Europe were as ambitious as they were unsuccessful. The sequestered monastic lands, especially, provided a strong vested interest among the new landlords, giving them a stake in the Reformation, a situation which Mary was not able to reverse. These things provoked one formidable rising, the Pilgrimage of Grace (Oct. 1536), in which political and economic motives played a part alongside religious conservatism. Like other 16th-century rebellions, it was crushed savagely.

The danger of isolation, in view of a papal council and a combination of his enemies, led Henry to put out feelers toward the German princes of the Schmalkaldic league, and teams of English and Lutheran theologians held conversations in Germany and England in 1536, 1538 and 1540. During this decade a number of eminent Protestant preachers occupied pulpits in London and elsewhere. The appearance of Coverdale's Bible (1535) and Matthew's (1537) was followed by an authorized Great Bible (1539), through the good offices of Thomas Cromwell. An Act of Ten Articles (1536) tried to regulate preaching, and *The Institution of a Christian Man,* known as the Bishops' Book (1537), provided homiletic and catechetical material, some of which derived from Protestant documents.

Once again a great royal servant fell for the unforgivable crime of bungling a royal match, and with the execution of Cromwell in 1540 the high tide of approach to the Protestants had been reached. The Act of Six Articles (1539) affirmed Catholic doctrine with savage penalties (which were not strictly enforced) and *The Necessary Doctrine and Erudition of any Christian Man,* known as the King's Book (1543), was a more conservative compilation than the Bishops' Book, though still Augustinian in much of its theology. Nonetheless, the noble achievement of Cranmer's English litany of 1544 heralded a liturgical genius, and in the last years of the reign Cranmer went ahead with preparations for further theological and liturgical change. Although the official variations from Catholic faith were few, and England was schismatic rather than heretical, by the end of the reign of Henry VIII the Reformation had permeated all classes of society and penetrated most parts of the country, was strongly entrenched in London, among the merchants, at the universities, and in the circles about the court, not least among ladies in the entourage of Queen Catherine Parr.

2. Edward VI.—Though the death of Henry VIII enabled the Reformers to proceed with boldness, the advent of the boy king, Edward VI, and of the council of regency brought a dangerous element of instability. The tolerant rule of the duke of Somerset as protector in the first part of the reign was openly sympathetic to the Reformers, and the ambitious duke of Northumberland, though he was much more of a ruthless politician, also was committed to the Protestant side. Meanwhile, assisted by Nicholas Ridley, bishop of London, Thomas Cranmer propounded and executed a number of controversial changes. Communion was restored to the laity in both kinds and a liturgy published to this effect in 1548. The remaining shrines and images were removed. A book of homilies was published, to be a norm of preaching, in which Cranmer set forth the Protestant doctrine of justification by faith alone. Toward the end of the reign a series of 42 articles, many of them influenced by continental confessions, were put out. More important were the prayer books which prescribed a uniform liturgy for the whole land, in the vernacular, both owing much to Cranmer himself. A fine achievement was the turning of the seven Latin choir offices into the congregational English services of matins and evensong. Within the limitations of 16th-century liturgical experience and Cranmer's own wide learning, the communion services in both books were notable. The service in the first Prayer Book (1549) was noticeably more conservative than that of 1552 which put forward a view of the Eucharist more congenial to the theologians of Strasbourg and Switzerland than to the Lutherans (*see* also COMMON PRAYER, BOOK OF).

Cranmer had the advice and counsel of a number of eminent refugees from among the continental Reformers. Two in particular, Pietro Martire Vermigli (*q.v.;* Peter Martyr) at Oxford and Martin Bucer at Cambridge, as regius professors, were able to influence a new generation, John Jewel being a pupil of Vermigli and John Bradford and John Whitgift (*q.v.*) among those influenced by Bucer. At court the silver-tongued Hugh Latimer exercised a prophetic ministry reminiscent of that of Zwingli at Zürich, and he and his friends, called "Commonwealth men" from their concern for society, attacked the hard-faced men of the court for their covetousness and self-interest. The tension between Reformers and radicals on the continent now was reflected in England, with

the infiltration of Anabaptists and the appearance of a Puritanism after the pattern of Zürich and Geneva in the persons of John Hooper and John Knox (*qq.v.*); it was conspicuous in the relation between the Stranger's church in London, which owed its rights to a royal charter and flourished independently of the impatient but helpless bishop of London.

3. Mary I.—Northumberland's desperate attempt to exclude a popish queen by putting Lady Jane Grey on the throne proved a disastrous fiasco, bringing all the council under shadow of treason, including Ridley and Cranmer. It underestimated the fund of loyalty and sympathy which Mary had won, as the daughter of the tragic Catherine of Aragon and of the great king. Herself an embittered and intransigent Catholic, she was earnest to undo the Reformation with a zeal which alarmed her uncle, Charles V, who counseled caution. England was still excommunicate, and the heresy laws had been repealed under Somerset, while the Prayer Book was still the lawful use. On one pretext or another the leading Reformers were imprisoned. Many scholars, clergy and gentlemen went into exile, some to intrigue in France, others to the centres of the Reformation in Germany and Switzerland. They took their theological differences with them, and the dissensions among the refugee congregation at Frankfurt, with a Prayer Book party led by Richard Cox and a Genevan party led by Knox, reflected a division which had been apparent under Edward VI and was to become a gulf under Elizabeth I. Mary lost sympathy by her unpopular marriage with Philip of Spain (July 1554). Nonetheless the patriotic and Protestant Wyatt's rebellion was soon crushed. The advent of Mary's royal kinsman, Cardinal Reginald Pole (*q.v.*), was the first step in the official reconciliation of England with Rome which took place solemnly on Nov. 30, 1554. The heresy laws were swiftly put back, and within a few days the trials for heresy began. Hitherto even Mary had had to use the legal instruments of royal supremacy, but now the authority of the church could be exercised by Mary and Pole in partnership.

The executions by burning were few in number compared with the pogroms on the continent. But they were compressed in time within a few months and concentrated in the southeastern counties. Although the majority of the 300-odd victims were of low estate (with a notable proportion of women), great publicity was attracted by the burning of a handful of Edwardian clergy. The execution of men of learning and high character, of Bishops Latimer and Ridley, of John Rogers, John Bradford and Rowland Taylor—above all, perhaps, the burning of an archbishop of Canterbury, Thomas Cranmer—these struck deep into the mind of England, a memory made permanent by the potent *Book of Martyrs* of John Foxe (*q.v.*). For Mary, the reign went from one disappointment to another. She gave Catholics a chance to breathe again, thus making it unlikely that Catholicism could ever be eradicated from England. But she was not able to restore the secularized lands and wealth of the church or to make more than a gesture of restoring the religious orders. There was no attempt to prevent the use of the English Bible. The failure of her marriage, her barrenness, the political disasters which ended in the loss of Calais, closed the reign in shadows which seem darker against the coming blaze of Elizabethan glory.

4. Elizabeth I.—Elizabeth I came to a throne beset by manifold and great dangers. With the country still at war with France, she proceeded in religious matters with caution which affronted the returning exiles and the Protestant old guard. She flirted with Lutheranism and with the possibility of protection under the peace of Augsburg. Though there were more contacts between the Elizabethan Church of England and the Swiss than are often supposed, they were with the godly magistracies of Zürich and Bern rather than that of Geneva, for with Genevan Calvinism Elizabeth had no sympathy at all. She pursued her own middle way, finding a great servant in William Cecil, Lord Burghley (*q.v.*), who kept the realm undiverted by the pressures of formidable court favourites and their cliques.

Throughout the reign there was tension between the queen and her house of commons; *i.e.*, between the "godly prince" and the proneness of the "godly magistrates"—increasingly Puritan in temper—to consider theological and liturgical change as within their province. In Matthew Parker (*q.v.*) Elizabeth found a scholarly and conservative archbishop of Canterbury. His consecration within the historic episcopate ensured that the Church of England, alone among the great churches of the Reformation, wittingly preserved the episcopate and the succession. But Elizabeth had no great opinion of her bishops, who in quality of mind and spirit are a poor contrast with her captains. The great leaders of the church had been disposed of in the fires of Mary's reign. After the disturbances of half a century, the clerical vocation was not attractive, and there was a long, hard struggle to improve the character and scholarship of the inferior clergy. Meanwhile medieval abuses persisted in a church which lacked the reforming benefits of the Catholic Council of Trent and which rejected the stern disciplines of Genevan Calvinism.

As was to be expected, the religious settlement was moderate. The queen was declared to be "supreme governor" of the realm —"as well in all spiritual or ecclesiastical causes as temporal." Parliament passed an Act of Uniformity which authorized the Prayer Book of 1552 with minor

adjustments, notably the changed words of administration in the communion service. In 1571 an abridgment of the 42 articles reached definitive form, and the Thirty-Nine Articles (*q.v.*) became the official confession of the English Reformation, remarkable for its moderation and its skilful ambiguities. Now the Church of England faced conflict from two sides. On the one hand the new Catholicism of the Counter-Reformation was of a very different temper from the seedy medievalism of Mary's reign. On the other hand a purposeful and thrusting new generation of Calvinists were determined to carry further the Reformation after the example of "the best reformed churches."

5. Catholic Recusants.—William (later Cardinal) Allen established a Catholic college for English exiles at Douai and Reims. The Reims-Douai Bible was published under his supervision. From the continent a succession of heroic and dedicated Jesuit missionaries infiltrated into the country. When in 1570 Pope Pius V in the bull *Regnans in excelsis* excommunicated Elizabeth, absolving her Catholic subjects from allegiance to her, a crisis of conscience arose for English Catholics, and a new political bedevilment entered a worsening situation. The growing severity of penal laws and the increasing number of executions (not unnaturally hailed as martyrdoms by the Catholics) accompanied the growing crisis of Protestant affairs in France and the Low Countries, while in England a succession of plots centred more and more in the figure of Mary, queen of Scots. Affairs reached a climax (1587–88) with the execution of Mary and with the great deliverance from the abortive invasion of the Spanish Armada.

6. Elizabethan Puritanism.—Puritanism (*q.v.*) was a movement "for the reform of Reformation itself" (John Milton) and for the remodeling of the church according to the Word of God. Its strength in this reign derived from a great movement in the University of Cambridge, centring in Calvinist doctrines of grace, predestination and conscience, and begetting an important Church of England Puritanism among clergy who specialized in moral theology and in pastoral care. These men were not much concerned with questions of church order, but the initial conflicts of the reign centred in the attempt to remove those clerical vestments which were despised by the radicals as remnants of popery. Now there was the more formidable attempt by a younger generation to set up the Presbyterian system within the Church of England. A new crisis developed when Thomas Cartwright, of Trinity college, Cambridge, put forward a doctrinaire Calvinism as the model for a Presbyterian Church of England, and in this was ably seconded in the writings of Walter Travers, of the Temple, London.

Archbishop Edmund Grindal (*q.v.*), who supposed that the "prophesyings" in progress among clerical groups were what he had known in exile—welcome means of clerical edification and education—had another view of the situation from the queen's agents who found in them a dangerous underground movement to set up within the church the *classis* (a meeting of clergy after the Genevan manner) and the Presbyterian system. His failure to deal energetically with the menace brought him into royal displeasure, but the queen soon found the minister she needed in a new archbishop, John Whitgift (an old antagonist of Cartwright at Cambridge). Whitgift evolved his own machinery, notably the prerogative court of high commission, some of whose methods, such as the *ex officio* oath, smacked of the inquisition and offended those of moderate Puritan sympathies, including Lord Burghley. By now Puritanism covered a wider series of movements than Calvinism. There were elements deriving in doctrine and ideal from the Anabaptists, new doctrines of the autonomy of each congregation, exercising the strict discipline of a "gathered church" and therefore not needing to tarry for the godly magistrate. There was a bitter literary war, and great stir was caused by the rough humour with which the anonymous Martin Marprelate tracts ridiculed the episcopate (*see* MARPRELATE CONTROVERSY). Some of the radicals were imprisoned and others driven into exile. Three of them, men of courage and high character, but perhaps with more zeal than discretion, John Penry, Henry Barrow and John Greenwood, were executed.

The literary apologetic for the Church of England did not go by default. In the earlier part of the reign John Jewel's noble *Apologia ecclesiae anglicanae* (1562) defended the church against Roman propaganda by setting it against the appeal to Scripture and the early church. The arguments of doctrinaire Calvinism were answered by Travers' fellow preacher at the Temple, Richard Hooker, whose *Laws of Ecclesiastical Polity* in sonorous and beautiful prose set forth a view of churchmanship which embraced reason and revelation, and left room for Christian liberties denied by Puritan Biblicism. At the end of the reign the apologists for the church, such as Hadrian Saravia and Richard Bancroft, stressed more and more the divine appointment of bishops against a Calvinism which found its church order in Scripture. Thus by the end of the reign of Elizabeth I the Church of England was not only established by law but was taking root in the affections of a nation, beginning to bring the first flowers of a piety based on the English Bible and the Book of Common Prayer, distinct from the spirituality either of the Counter-Reformation or of continental Protestantism. But the Catholic recusants, too, had proved their own faith and loyalty, while the diversities of Puritanism indicated that the religious tradition of the English could not be permanently confined within one national uniformity of worship, belief and discipline. (*See* also ENGLAND, CHURCH OF; ENGLISH HISTORY.)

7. Ireland.—England's treatment of Ireland is a black page in Reformation history. The country was conquered, and the conquerors dealt with it after the brutal fashion of that time. Few Catholics lost their lives for religion pure and simple, as apart from political revolts; but a series of unjust penal statutes were enacted, and these, although seldom enforced in their full theoretical strictness, were relaxed far too slowly in the face of advancing civilization; instead of weakening, they strengthened the attachment of the Irish to their religion. (*See* also IRELAND, CHURCH OF.)

V. OTHER COUNTRIES OF EUROPE

1. Geneva and John Calvin.—The city of Geneva has special significance among the cities of the Reformation as a centre of French-speaking Switzerland, and its Reformation under its great leader John Calvin (*q.v.*) ushered in a new period of Protestant history and marked the emergence of the Reformed, as distinct from the Lutheran, tradition. In the struggle for independence from its bishop, and from the house of Savoy which was trying to extend its influence over the city, Geneva was drawn into the orbit of the thriving and aggressive city of Bern, which had been reformed in 1528 and exerted pressure on the course of events in Geneva in the following decades. The first fiery herald of the new evangel was the ebullient Guillaume Farel (*q.v.*), whose preaching made headway despite fierce opposition. In May and June 1535 public disputations were held, ending in the solemn resolution by the council, with uplifted hands, to live according to the Word of God. The initial success was swift but premature. This was the situation when John Calvin passed through the city, intending to devote his life to scholarship, for which his legal, humanist and theological studies had remarkably equipped him. He yielded to Farel's earnest conjurations to join the battle for reform and began that uneasy marriage of convenience with the city of Geneva which was to be fruitful beyond his dreams and was to persist until his death.

Dispute with the magistrates about the disciplinary rights of the clergy and some interference from Bern led to the exile of Farel and Calvin in 1538. Calvin spent three important years as pastor

of the French congregation in Strasbourg where he learned much from Bucer and his colleagues. He returned to Geneva at the request of the city, which was now prepared to accept his program, memorably enshrined in the *Ordonnances ecclésiastiques* (Nov. 20, 1541). Calvin now emerged as a great preacher and teacher. His formidable patristic learning was exceeded by his skill as a biblical expositor, and he produced a great series of commentaries on Holy Scripture. In his *Christianae religionis institutio* (*Institutes of the Christian Religion;* 1536, with revisions and additions in several editions before the definitive edition, 1559) he achieved one of the great documents of European history, a summary of biblical theology which the growing class of educated laymen as well as clergy could understand. In it he set forth the Augustinian doctrines of grace, divine sovereignty and predestination, and a good deal of Luther's teaching about salvation. But he also emphasized the importance of the visible church and of the pastoral office. Calvin found in Scripture a fourfold ministry of pastors, teachers, deacons and elders and made this the foundation of a coherent, workable system of Christian discipline. Moreover, his attitude to the state and to civil government was positive at a time when even in Germany events had brushed aside Luther's separation of the spiritual and temporal power. Here was a new shape for Protestantism, tired and slowing down in its second generation, and one which could be exported with powerful effect, more forward-looking and perhaps more democratic in temper than Lutheranism.

Thus Genevan Calvinism took into itself many elements, including the achievements of Zürich, Basel and Strasbourg. Calvin carried through liturgical reforms, and psalm singing became an important feature of Reformed worship. Reformation in the cities always included oversight of public morals, and in Calvin's last years a new austerity touched almost every aspect of civic life. Despite a persistent opposition party, and criticism of his intolerance (in the exile of the schoolmaster Sébastien Castellio for his radical tendencies and in the impeachment and execution of Michael Servetus for his anti-Trinitarian and Anabaptist views), Calvin's prestige stood high, and as a centre of reform Geneva now ranked with Luther's Wittenberg. From Geneva, trained, dedicated pastors went into France, in some ways a heroic Protestant counterpart to the Jesuit missionaries of the period. Calvin was succeeded by a theologian and administrator of great ability, Theodore Beza (*q.v.*). (*See* also REFORMED CHURCHES.)

2. Scotland.—Scotland shared the ills of the medieval church; the weakness of the crown and the entanglement with France both complicated and prolonged the struggle for Reformation, which to some extent took on the character of a national movement for independence from France. There is evidence of Lollard influence during the 15th century. Contacts with humanism and the study of Greek, Latin and Hebrew depended on students abroad, and there was no circle to compare with that of the Oxford and Cambridge humanists in England. In the 1520s Lutheran books began to circulate and in 1525 were formally prohibited by act of parliament. The first Protestant of distinction was the well-born Patrick Hamilton, a scholar who had been to Wittenberg and had been associated with Franz Lambert at Marburg. His collection of evangelical commonplaces, *Loci communes* (familiarly called "Patrick's Pleas" or "Places") were translated (1528) by the English martyr John Frith. Hamilton was burned at St. Andrews at the age of 24. The next martyr was George Wishart (*q.v.*), a learned divine who had taught at Cambridge and on the continent. When he was burned in 1546 a band of nobles avenged his death by murdering the cardinal archbishop David Beaton.

Among Wishart's associates was John Knox (*q.v.*) who was captured during the aftermath of the Beaton murder and spent some time in the French galleys. He was a man of powerful and intransigent temper, but with humour and common sense and courage. During his stay in England in the reign of Edward he was popular as a preacher in the Lollard areas and favoured by Northumberland as a goad to Cranmer. Exiled in the reign of Mary, he became minister to the English exiles at Frankfurt but quarreled with them over the form of church service. He then went to Geneva, where he became a wholehearted Calvinist and where he preached those sermons, the inspiring effect of which an English ambassador compared with the noise of 500 trumpets and 1,000 drums. He produced for the exiles a Genevan service book. He also wrote the indiscreet tract, *The First Blast of the Trumpet Against the Monstrous Regiment* [*i.e.*, rule] *of Women,* which successfully closed the England of Elizabeth I against him. He returned to Scotland in 1559. But though Elizabeth liked Knox little and Calvin less, it was imperative for England to offset the Franco-Scottish alliance, and armed forces were dispatched which caused the withdrawal of the French, Knox leading a great service of thanksgiving for "our confederates of England." An attempt at a moderate Counter-Reformation was launched by Archbishop John Hamilton in three national councils (1549, 1552, 1559) and produced a moderate Catholic catechism influenced by the Augsburg Interim (1548) and the theology of Johann Gropper. During critical months when the queen was absent, the Scottish parliament went ahead with reform, abolished the authority of the pope in Scotland and forbade celebration of the Mass. A confession of faith was drawn up, with Knox as principal author. This, the first Scottish Confession (1560), is the most forthright of all the Protestant confessions of the age. A Book of Discipline was also prepared, adjusting the Calvinist polity to the Scottish situation.

This direction from the centre was accompanied by the growth of many "privy kirks," while congregations met also in the houses of the gentry. In 1562 provincial synods were appointed, and in 1564 a revised form of Knox's Genevan liturgy became the official Book of Common Order (*see* COMMON ORDER, BOOK OF). The extent to which the Reformation in Scotland was determined by Calvinist blueprints must not be exaggerated, and the first Scottish Reformers were by no means determined to abolish bishops. Not until 1581 was a Second Book of Discipline adopted and the principle of the equal rank of all ministers declared and established. By then Knox had passed from the scene, but the cause of Calvinism found another champion in Andrew Melville (*q.v.*) who had lived in Geneva and was devoted to the Calvinist polity. His political influence was great, but memorable too was his great work for education in Scotland, both in schools and universities. Despite the entanglements with political intrigue in high places, the Reformed church in Scotland was not, as in France, cut off from the people, and it took deep root in the common life of the whole nation. (*See* SCOTLAND, CHURCH OF; PRESBYTERIANISM.)

3. France.—Even more than in Scotland, the Reformation in France was involved in the political struggles between the crown and the nobility. The concordat of 1516 had confirmed royal authority in the church, and Francis I was a Renaissance prince more splendid and more ruthless than England's Henry VIII. During the 15th century France had produced outstanding theologians (Jean de Gerson and Pierre d'Ailly) and the Sorbonne had been the citadel of the conciliar theory which offset the canonist doctrines of the papal plenitude of power. On the eve of the Reformation there were clerics of eminence and reforming zeal—*e.g.*, Jean Standonck and Jean Vitrier, the friend of Erasmus. So strong was the humanist circle in Paris that it was said to be more important than Rome in the field of letters. Supreme among these, in the range of his interests and learning, was Jacques Lefèvre d'Étaples (*q.v.*). By reason of his biblical studies, his edition of the Psalms and his commentaries on St. Paul, he is often hailed as a reformer on the eve of the Reformation; but this is to ignore the eclectic character of his mind, to which his editions of Aristotle, of the Church Fathers, of medieval mystics and of the Hermetic writings bear witness.

As elsewhere, the writings of Luther circulated swiftly in France, and one of the first martyrs was the scholarly Louis de Berquin, who had translated many writings of Erasmus. Soon the church in France was to become a martyr church, commemorated in the martyrology of Jean Crespin (1554), who anticipated the equally potent *Book of Martyrs* of the Englishman John Foxe. Affairs went on in a series of crises. One came in 1533 when the rector of the University of Paris, Nicholas Cop, uttered a plea for toleration in his rectorial address which caused a flurry of panic. Then in Oct. 1534 Catholic opinion was alarmed and shocked when placards virulently attacking the Mass were found in the streets

and in the royal palace. Many of reforming sympathies were forced to flee, some scholars taking refuge with Guillaume Briçonnet, bishop of Meaux, and later finding safety at the court of Marguerite de Valois, queen of Navarre. The poet Clément Marot was among them who, though no Lutheran, translated many Psalms, and his beautiful work was influential for French Protestant worship, alongside the translations of Theodore Beza.

A Protestant party quickly grew, supported by a number of more discreet sympathizers whom Calvin called "Nicodemites." They became known as Huguenots, and soon had eminent supporters among the nobility, such as the prince de Condé (Louis I de Bourbon), Adm. Gaspard de Coligny and Duplessis-Mornay. Individual executions began to give way to massacres, and in 1545 about 3,000 Waldensians were brutally done to death. Under Henry II the legal *parlements* took the initiative and soon the prisons were full. The year 1559 was in some ways a turning point. It saw the execution of the eminent French layman Anne de Bourg. It also saw the organization of the scattered Protestant congregations, for an important synod met in Paris and drew up a confession of faith which owed much, though by no means everything, to Calvin. For, despite Calvin's constant interest and incessant correspondence, and the scores of pastors who came to France from Geneva, the French Reformed Church managed its own life, had its own characteristics.

Now began a struggle between the Huguenots and the house of Guise. Attempts at compromise and acts of ruthlessness went on side by side. At the colloquy at Poissy in 1561 the Jesuit theologians faced in debate Theodore Beza and the aged Peter Martyr. But the massacre at Vassy in the following year showed the fierceness of Catholic opposition to reform. Then in 1570 an armistice was called and by this peace of St. Germain-en-Laye toleration was granted and an amnesty, and the Huguenots were allowed the four fortified cities of La Rochelle, Montauban, La Charité and Sognac. Worship was permitted in the homes of the nobility, but not in congregations—a move which cut off the growing movement in some measure from the common people. But in 1572 came the terrible Massacre of St. Bartholomew's day (*q.v.*) in which first Admiral Coligny and then many thousands (between 20,000 and 50,000) perished in Paris and in the rest of France.

BY COURTESY OF ARCHIV FÜR KUNST UND GESCHICHTE, BERLIN

THEODORE BEZA, BY AN ANONYMOUS MASTER OF THE FRENCH SCHOOL, 1605; IN THE ARCHIV FÜR KUNST UND GESCHICHTE, BERLIN

This by no means mortal blow only strengthened the Huguenots' resistance, ending an internal struggle about the rights of the congregations, and a democratic view of church polity which had found such formidable champions as the philosopher Petrus Ramus. A growing number of "Politiques," a section of the Catholics led by the duc d'Anjou, came to regard toleration of some kind as the only preventive against anarchy and chaos, and this policy triumphed in the Edict of Nantes (1598; *see* NANTES, EDICT OF). This made large concessions to the Huguenots, allowing them freedom of conscience and liberty of worship in many areas of France, giving them public rights both to hold public assemblies and maintain 200 fortified places and garrisons. The recognition of the Reformed Church as a powerful entity within the state was ominous, since it was obvious that if ever France found its unity under an absolute ruler, such as Louis XIV was to prove, he would not be able to tolerate such a challenge to his power. (*See* also HUGUENOTS.)

4. Holland.—In the Netherlands the struggle for Reformation was protracted by reason of severe persecutions in a land which was under the direct rule of the emperor and because the cause of Reformation became bound up with the cause of liberation from Spain. In the 17 provinces there was a cultural and religious setting favourable to new ideas—thriving commercial towns in a land which had been the home of the late medieval *devotio moderna* and where the influence of the native Erasmus was marked. As usual, Lutheran influence came first, and two members of Luther's Augustinian order, Heinrich Voes and Johann Esch, were burned in Brussels in 1523. An imperial ordinance of great severity against the new opinions and against those who possessed forbidden heretical literature was passed in 1529, and other fierce edicts followed in 1535 and 1538. But conservative Lutheranism did not suit Dutch austerity and zeal, while Luther's emphasis on civil obedience could not please a nation restive under its foreign overlords. There was a swift development therefore of the Anabaptist movement. This, under the pressure of savage persecution and the death of thousands of humble victims, developed an apocalyptic fervour and contributed to the Anabaptist disaster at Münster where a fanatical chiliastic theocracy, under siege by both Protestant and Catholic forces, was finally destroyed with extreme atrocities in 1535. Meanwhile there was steady infiltration of Protestant literature, and of importance were the writings of the Swiss Reformer Heinrich Bullinger and a vernacular manifesto produced in Anastasius Veluanus' *Leken Wechwyser* ("Guide for the Laity"). Calvin, whose wife came from Lille, kept in sympathetic touch with the growth of a Reformed church which became the dominant form of Dutch Protestantism.

A lull in persecution (1540–45) gave the Reformed churches a chance for growth and consolidation, and the writings of Calvin were reinforced by the powerful preaching of Pierre Brully. In 1561 a confession of faith, the *Confessio Belgica* (the work of Guy de Brès) was published. The Dutch were now determined to be free from Spain, and in 1559 William I the Silent, prince of Orange, urged the states-general to press for the withdrawal of the Spaniards from the land, though not until 1573 did he become Protestant. Amid the fervour of a church struggle which was also a national revolt, violence was inevitable. Such incidents as the wrecking of the interior of Antwerp cathedral in 1566 gave excuse to Philip of Spain and his advisers for still more desperate repression under the dictatorship of the duque de Alba, which succeeded only in uniting the Dutch more closely together. In 1584 William was assassinated. Yet by 1609 the Dutch were strong enough to force upon Spain a 12-year truce which meant the establishment of the Dutch republic. Protestantism was now firmly established in the northern provinces, at the cost of a divided land, since the cause of the Reformation had been stamped out in the ten provinces of the south. In Holland, however, the strict Reformed discipline was established, in which the spirit of freedom and independence was embodied in such pronouncements as that of the synod of Emden that "no church may pretend to domination or pre-eminence over the other churches." This was the beginning of a great half-century for Holland when Dutch art and Dutch theology dominated western Protestantism.

Although strict Calvinism prevailed, it was in Holland that the formidable protest of Jacobus Arminius (*q.v.*) was made against the rigid doctrines of predestination and election. His "Remonstrant party," so-called after the Remonstrance (1610) which asserted in five points the freedom of man's will, became an important rallying place for opposition to Calvinist rigorism (*see* ARMINIANISM). But the Synod of Dort (*q.v.*) in 1619 formally declared the five articles of Calvinism, unconditional election of the predestined, atonement limited to the elect, the total depravity of man, the irresistibility of grace and the perseverance of the saints.

5. Scandinavia.—In Scandinavia, as in England, the crown determined the speed of the Reformation. The hegemony of the kings of Denmark over Norway and Iceland, and the rule of Gustavus I Vasa in Sweden and Finland, imposed the Reformation from above and carried through the secularization of church property.

Denmark.—The turbulent and ruthless Christian II was prepared to use the Reformation in his complex struggle with dissident

elements in his dominion, and sought, in 1521, the not very wise advice of the Wittenbergers Martin Reinhardt and Andreas von Karlstadt. But his plans were defeated and he went into exile in 1523. His successor, Frederick I, broke with Rome and furthered Lutheran influence. In Denmark there was a bridge between humanism represented by Paul Helie and Reform represented by Christiern Pedersen (*q.v.*); both were reinforced by Hans Tausen (*q.v.*), "the Danish Luther." In 1529 Pedersen produced a Danish New Testament. A Danish confession of faith (*Confessio Hafniensis*) lacked authority and was superseded in 1536–37 when Lutheranism and the Augsburg Confession were formally adopted. The new church received its church order from Luther's colleague Johann Bugenhagen, who ordained seven superintendents for the reorganized church.

Norway and Iceland.—Norway was culturally and economically more backward than Denmark, and its Reformation was imposed from above by the Danish crown at the same time (1536–37) as that of Denmark. In Iceland after a bloody struggle reminiscent of Viking times the Reformation was imposed by Denmark. The second evangelical bishop, Gudbrandur Thórlaksson, translated the Bible (1584) into Icelandic and produced an Icelandic liturgy.

Sweden and Finland.—The Reformation in Sweden owed most to four men, the ruler Gustavus I Vasa, the archdeacon Laurentius Andreae (Lars Andersson), and the two gifted Reformers, the brothers Olaus and Laurentius Petri (*q.v.*). One feature of the Swedish Reformation, important for its future, was the preservation of the apostolic succession, in the consecration of three bishops in 1528 by royal command and without papal confirmation but using the Catholic rite. In Finland the notable Reformer was Mikael Agricola, a former Wittenberg student who wrote a Finnish catechism and translated the New Testament and much of the Old Testament into Finnish.

The religious Reformation in Scandinavia owed much to Lutheran initiative, to the work of Bugenhagen and to the labours of a number of Scandinavian Reformers who themselves had studied at Wittenberg. Thus these lands became more thoroughly Lutheran even than Germany itself, and almost complete Lutheranism has persisted there.

6. Central and Southern Europe.—In eastern Germany, Lutheranism was advanced by the conversion of the grand master of the Teutonic Knights, and in 1554 the diet of Wolmar declared Livonia to be Lutheran. In Poland a complicated political structure and a heterogeneous population with no strong central authority led to a diversity of Protestantism, including radical Anabaptists, Lutherans, Calvinists and the Unitarianism of the Socinians introduced by Faustus Socinus (*q.v.*). The Compact of Warsaw (1573) affirmed religious liberty for differing religious groups which, however, were ill equipped to meet the challenge of the Counter-Reformation formidably led by the Jesuits. In Bohemia, Lutheran influence touched the various parties in the Hussite churches, and there was Lutheran infiltration among scholars and among the nobility. In Moravia there was an Anabaptist movement, especially at the time of the refugee settlement around Nicolsburg in 1527. Political divisions in Austria made it difficult for the archduke Ferdinand to control events, and despite strong persecution a number of young men from noble houses studied in Protestant universities, while some of the gentry used Lutheranism against the Habsburg rulers. In Hungary, however, a Lutheran minority became strongly entrenched, finding its way at first into the German elements of the population and making headway in a land where the Catholic ecclesiastical structure was crumbling before Turkish invasion. But some found more congenial the second wave of Reformation with its Zwinglian and Calvinist doctrines.

Spain and Italy were to be the great centres of the Counter-Reformation, and in Spain itself a Catholic Reformation had begun under the work of Cardinal Francisco Jiménez de Cisneros (*q.v.*), which also produced the Reformed breviary of Cardinal Francisco de Quiñones, while the Complutensian Polyglot Bible was the monumental achievement of the Spanish humanists of Alcalá. There were a number of mystical groups in some ways reminiscent of the Anabaptists, but within the Catholic framework and powerfully influenced by Erasmus. The two lay scholars Alfonso and Juan de Valdes were more evangelically inclined, and Juan exercised fruitful influence in Italy. There were groups of so-called Lutherans at Valladolid and Seville. Francisco de Enzinas (*q.v.*; called Dryander) translated the New Testament into Spanish but spent most of his career outside Spain. The most famous of Spanish Protestants was the medical scholar and anti-Trinitarian Michael Servetus.

In Italy, though there was widespread criticism and even skepticism in humanist circles, there were obvious difficulties to the spread of Protestantism in the land of the papacy. Among the many diverse cities and territories of a much-divided land, Venice and Padua offered some protection to Protestants who tended to extreme views. The great Italian preacher Bernardino Ochino (*q.v.*), vicar-general of the Capuchins, went into exile and developed radical views about the Trinity, opinions held in an even more extreme form by the lawyer Laelius Socinus. The greatest Italian Reformer was Pietro Martire Vermigli (*q.v.*), an eminent Augustinian, whose Protestantism, developed in Switzerland, England and Strasbourg, was of a Reformed, perhaps Zwinglian pattern.

VI. RADICALS, ANABAPTISTS AND SPIRITUALISTS

From the beginning of the Reformation movement a body of opinion favoured something more drastic than Luther's bold conservatism. The Puritan iconoclasm of Karlstadt and the apocalyptic violence of Müntzer found support among peasants and artisans, and the writings of both men had lingering influence after the collapse of the Peasant War in Germany. There was criticism of the biblicism of Wittenberg and its deference to secular authorities. The three laymen known as the Zwickau prophets had denounced infant baptism, influenced perhaps by its repudiation in extreme Hussite circles in Bohemia. They had attempted to set up a small community of the elect at Zwickau but in 1521 settled in Wittenberg, whence they were banished by Luther in 1522.

But though infant baptism was denounced in radical circles, it was not until 1525 that the practice of rebaptizing adults began, and it is possible to speak of an Anabaptist movement. This had its origins in Zürich, among the "Swiss brethren," a group of young intellectuals in the entourage of Zwingli, who rebelled against Zwingli's apparent subservience to the magistrates and his reluctance to proceed swiftly with thoroughgoing reform. Their leaders were Conrad Grebel (*q.v.*), of patrician family, a highly educated humanist converted to a narrow biblicism; Felix Manz, also a scholar; and the former priest Georg Blaurock. A series of debates only widened differences with Zwingli, and the sacrament of baptism became the focus of a divergence which embraced different views of the nature of the church, of Christian discipline and of civil government. The first adult baptisms took place at Zollikon outside Zürich at the end of Jan. 1525, and soon something like a mass movement was in progress, particularly strong in Sankt Gallen. The vehemence and intransigence of the leaders, the revolutionary implications of their teaching, led to their expulsion from one city after another, which simply increased the momentum of an essentially missionary movement. Soon the cities took sterner measures and most of the early Anabaptist leaders died in prison or were executed. The Schleitheim Confession (1527), drawn up under the leadership of the Anabaptist Michael Sattler, was not so much a public apologia as a document related to extremist elements within the Anabaptist camp.

In south Germany the Anabaptist movement had its own characteristics and was perhaps bedeviled by an apocalyptic strain which persisted from the time of Müntzer. It found a missionary preacher of power in Hans Hut, a disciple of Müntzer who replaced Müntzer's violent program with a dated eschatology calculated also to provoke unrest. He was rebaptized in Nürnberg in 1526 by Hans Denck, in whom radical ideology was softened by Johannine theology. Denck and Hut seem to have presided at two "synods" of Anabaptists in 1527, but after some months of exile Denck withdrew from the movement. Balthasar Hübmaier was a learned theologian of ebullient spirit, who led reform in the

Black forest town of Waldshut until expelled by the Austrian troops. He wandered from city to city, adopting Anabaptist views but differing from most Anabaptists in accepting civil government and defending the use of force. In 1527 he joined the refugee stream to Nicolsburg in Moravia, where the Anabaptists found temporary asylum, and ran into a great number of south German Anabaptists encouraged by Hut to believe in the imminence of the Second Coming of Jesus Christ. There was a disputation between the two leaders, Hübmaier repudiating Hut's eschatology, which named a date for the millennium, and affirming the authority of the magistrates. Hut died in prison in the next months and Hübmaier was executed. The difference was important between the so-called *Schwertler* ("Sword") Anabaptists, who supported the use of force, and the *Stäbler* ("Stave") Anabaptists, who rejected all violence. In central Europe the radical form persisted and set up communities in which a limited communism was practised.

The apocalyptic strain continued in the visionary Messianism of Augustin Bader and Melchior Hoffman (*q.v.*). Hoffman, in jail at Strasbourg, both flattered and horrified the magistrates by announcing that their city had been chosen to inaugurate the new age. The savage persecution of this martyr church has no doubt to do with the emotional extravagances and with an ugly streak of fanaticism which began with the fratricide in Sankt Gallen, when Thomas Schugger decapitated his brother Leonard "in the Spirit," and continued until the development of polygamy at Münster. But there was also a solid core of simple fervent piety which impressed the Strasbourg Reformers Capito and Bucer, who also induced Philip of Hesse to pursue a tolerant and profitable policy. In the layman engineer, Pilgram Marpeck, the south German Anabaptists found a leader of considerable moral stature and one whose sincerity and deep biblical learning were of great importance for the development of the movement at a dangerous stage in its affairs, when it might have been unbalanced by apocalyptic visionaries.

In Holland the movement grew swiftly and here again Messianism appeared in the figure of David Joris (*q.v.*). Savage punishment led again to a refugee movement which aroused the fatal hope finding the city of refuge in Münster, Westphalia. During its siege (1534–35) the leadership passed from Jan Mathijs to the schizophrenic John of Leiden (Jan Beuckelson), whose insane brutality, added to the scandal of public polygamy, brought appalling publicity upon the movement, widely discrediting it in the eyes of all authorities, just at a time when it had thrown up a leader of noble piety and moderation in Menno Simons (*q.v.*).

The Anabaptist movement must not be oversystematized. It was a congeries of radical groups, shading off into other forms of radicalism, which included those who would give allegiance to no form of reformed Christianity. Such were Sebastian Franck (*q.v.*), the chronicler, and his friend John Campanus, author of *Contra totum post apostolos mundum* ("Against All the World From the Time of the Apostles") and the Silesian nobleman Kaspar von Schwenckfeld (*q.v.*), who developed eccentric Christological and eucharistic doctrines, about which he wrote controversial tracts and which attracted some adherents. In addition to departures from orthodox Christology, there was the development of anti-Trinitarian arguments, by Ludwig Hetzer and by the obstreperous and violent Michael Servetus (*qq.v.*), while in the writings of Bernardino Ochino (*q.v.*) are to be found the beginnings of Unitarianism.

VII. ASSESSMENT OF FUNDAMENTAL ISSUES

It is inevitable that there should be controversy about the meaning of the Reformation. It was a revolution which affected not only religion but other spheres of life. Its drastic program attacked not only generally acknowledged abuses but beliefs and practices which many Christians preferred to retain, distinguishing between needful reforms and revolutionary schism. Moreover, revolutions seldom fulfill the hopes of their makers, and the Reformation movement became caught up in political and social pressures in which religious men and their ideals were dwarfed. Yet the Reformation cannot be understood unless it is realized that Catholics and Protestants alike believed that the gravest issues were at stake for which men must be prepared to die. Had the Reformers been asked what it was all about, they might have said that it was a conflict about the Word of God. One way and another, their creative first works centred here.

To understand the Reformation it is necessary to give full weight to the underlying theological and religious convictions which sustained it. During the 16th century basic Christian doctrines and ideas were argued, examined and redefined. It would be an oversimplification to suggest that these were at all times and everywhere the dominant causes of a revolution complex in origin and dependent on a variety of historical, political, social and economic circumstances. None the less the sequence of events which began with Luther's 95 theses and within Christendom, and ended in the separated nations and divided churches of the modern world, cannot be understood without constant reference to those religious beliefs.

The Reformation began with a crisis of conscience, embodied in the spiritual struggles of Martin Luther. Through him the doctrine of justification by faith gained priority on the Protestant theological agenda. The doctrine that salvation is a divine gift had been at the heart of the theology of St. Paul and St. Augustine and was never lost sight of in medieval theology. But the Reformers sought to safeguard this truth against a legalistic religion of works and merit, what Gilbert Burnet called a "superannuated Judaism." The doctrine of salvation "by faith alone" was intended to emphasize, once and for all, that the ground of the Christian hope is in the forgiving mercy of God, displayed to mankind in Jesus Christ and apprehended by faith.

The assertion of man's personal experience of God, as opposed to his acceptance of the authority of the church and its mediation, led inevitably to emphasis on the authority of Scripture, interpreted not by tradition but by the guidance of the Holy Spirit. Although this led to extreme Puritanism, which condemned all not expressly ordained in the Bible, and to fundamentalist belief in the Bible's literal truth and equal value, in the early Reformers, at least, it was joined with a scholarly attitude to biblical texts and to a testing of the value of its parts by the extent to which they conformed to Christ's revelation of God. The Bible was to be understood as a revelation of salvation in the light of reason and scholarship, and was seen to have supreme authority. Thus the Reformers repudiated the papal plenitude of power and set against it the authority of the Scriptures, interpreted by the Holy Spirit through the Christian church and the consciences of Christian men. Though they rejected the "traditions of men"—unscriptural infiltrations in faith and worship unsupported by, or even contrary to, the witness of the Bible—the Reformers did not reject tradition; they themselves appealed to the Church Fathers, the councils and the life of the early church.

Thus the Bible had great importance in the age of the Reformation. Vernacular Bibles existed and were printed before the time of Luther, but the innumerable editions of Luther's translation led the way in one country after another to the use of the vernacular Bible. These were the work of scholars using the humanist tools of languages and critical method. The new translations heralded a new method of exegesis and of preaching. Especially influential were the commentaries of Calvin and Bullinger, and Luther, Zwingli, Knox, Latimer were among the outstanding Christian preachers in church history. There is testimony from Catholics, such as Johann Faber, that the Reformation did indeed bring into being a new and virile form of biblical exposition, while the emphasis on the Word of God meant a reorientation of the place of preaching in the office of a minister and in the life of the worshiping congregation. One should not mention the fine, outstanding preachers without noting how concerned they were at the low level of most of the clergy in this matter; the provision of books of homilies and the long battle for an educated clergy in the England of Elizabeth I shows what a grave problem this was. (*See* also PREACHING.)

St. Paul and St. Augustine stressed the grace of God, the divine love and the divine initiative which evokes, accompanies

and brings to fulfillment the human response to the calling of God. God predestined those whom he would save, in Christ, before the foundation of the world. Problems concerning this election and predestination, and concerning the fate of the nonelect, or reprobate, were a constant medieval theme, and the Reformers continued an already ancient and intricate debate. Calvin systematized the teaching of earlier Reformers like Luther and Bucer. Divine grace was contrasted with the total depravity of men since the Fall. A double predestination of elect and reprobate was affirmed. To those elect and called, all needful grace, including that of final perseverance, would unfailingly be given. It must be remembered that in practice this did not lead to a passive quietism but to the courageous independence of the Dutch patriots or the Scottish Covenanters. None the less, the dualism of the system, the uncertainty about a man's own election, brought problems of conscience which Puritan moral theology tried but on the whole failed to resolve. (*See* also PREDESTINATION.)

All the Reformers agreed that Christ's sacrifice for the sin of the world was made sufficiently, once for all, on the cross. This affected their attitude to the Eucharist and to the ministry. The medieval priest's first duty was to celebrate the sacrifice of the Mass: the new ministers and clergy were to preach the Word and to administer the sacraments, sharing with their people the only acceptable sacrifice of prayer, praise, penitence and thanksgiving. In their thought the communion of the faithful dominated the idea of sacrifice. To this end they restored to the laity communion "in both kinds" (the cup had been withheld from them during the middle ages). But if they agreed about repudiating the Mass, they were grievously divided over the nature of the divine presence in the Eucharist.

Martin Luther's belief in the real presence was a consequence not of scholastic reasoning, but of simple acceptance of the literal meaning of the words of Christ, "This is my body," which meant for him the presence of the whole Christ, God and man, with his faithful people. This meaning was challenged first by Luther's colleague Karlstadt and then by Zwingli, while Oecolampadius brought the support of his patristic learning to the alternative doctrine of a true but spiritual presence. The Strasbourg theologians supported the Swiss, the Swabians Luther, in a debate which became more and more bitter. At the conference at Marburg in Oct. 1529 the leading theologians on both sides conferred and debated but came to no agreement about the Eucharist, and the hope of a common political front was smashed on the eucharistic division. One consequence was that Bucer realized that he had misunderstood Luther to mean a local, physically circumscribed presence and henceforward was earnest in trying to reach agreement which he achieved in the Wittenberg Concord (1536). This brought the Strasbourg and Wittenberg theologians together but failed to win the Swiss. Calvin developed his own stresses in doctrine, which were of a mediating kind, and in 1549 achieved the agreement with Zürich (the *Consensus Tigurinus*) which made possible the consolidation of the Reformed, as distinct from the Lutheran churches.

The first textbook of the new theology was Philipp Melanchthon's *Loci communes rerum theologicarum* (1521), superseded by the majestic 1559 edition of the *Christianae religionis institutio* of Calvin. The martyrologies of Jean Crespin in France and John Foxe in England helped to sustain for centuries the memory of persecution. The conflict with Catholic authorities, with pope, emperor and the Council of Trent, as well as internal conflicts in the Protestant ranks, produced some important confessions of faith, of which outstanding examples are the Lutheran Augsburg Confession (1530), the First Helvetic Confession (1536), the Scots Confession (1560) and the Thirty-Nine Articles (1571) with the Anabaptist Schleitheim articles (1527). (*See* also CONFESSIONS OF FAITH, PROTESTANT.)

The Reformation produced far-reaching liturgical experiments and changes, not least those involved in the general repudiation of the Mass and the restoration of communion in both kinds to the laity. Thomas Müntzer and Thomas Cranmer both achieved a creative feat by turning the Latin medieval choir offices into vernacular services for the congregation. In the new rites of the Eucharist, the communion of the faithful and the commemorative aspect dominated or excluded the thought of sacrifice. Luther's German Mass (1526) was the forerunner of numerous church orders in Lutheran lands, and other notable centres of liturgical reform were Strasbourg and Geneva. Zwingli and the Anabaptists sought and in part achieved the supposed simplicity of the original apostles. The new emphasis on the priesthood of the believing congregation gave hymn- and psalm-singing an important place in Protestant worship. The Reformers themselves wrote fine hymns, and Wittenberg, Strasbourg, Constance and the Anabaptist congregations produced hymnbooks.

That the Word must be heard and understood was a principle which resulted in a stress on education. The work of Luther and Melanchthon in Germany was paralleled by the schools of Johannes Sturm in Strasbourg and Theodore Beza in Geneva. Among many catechisms, noble documents are Luther's children's catechism and the Heidelberg catechism of the Reformed Church.

Though the Reformers repudiated the papacy and a Catholic theory and rite of ordination, they did not disavow church order or a regular and ordained ministry. Differences in emphasis led to the differences in forms of church government. The Lutherans believed that every church had the right to establish its own order, in conformity only with the example of the early church as described in the Bible. No order was divinely ordained, so that some discretion could be allowed to each church to act according to external circumstances. This attitude was also, in the main, adopted by the Reformers in England, and there, as in the German states and in Scandinavia, the Reformed (Lutheran) church became also the national church. Calvinists, on the other hand, laid down an order of church government deriving its authority from its members—a spiritual democracy, in fact—imposing, however, a high degree of discipline and, although independent from the state, using secular power to enforce its rule. Their attitude to episcopacy varied. The churches of England and Sweden retained the historic episcopate within the apostolic succession, but for the most part the Reformers regarded continuity of doctrine as more important than succession of order. In some Lutheran lands and in some Reformed churches, the office of bishop was retained. For both Lutheran and Reformed churches it was essential that ministers of Word and Sacrament should be properly called and lawfully appointed. Calvin, and the Reformed churches generally, rejected the monarchical episcopate which elevates one minister above others, and returned to what was thought to be the practice of the early church as deduced from the New Testament—that of a parity of ministers, together with the office of lay elder. Among radical groups in England and on the continent of Europe there were those who stressed the autonomy of each congregation and its capacity to call and appoint its own minister. In opposition to the idea of a national church or *Volkskirche*, the Anabaptists set forward the ideal of a church of believers, kept pure from the world by strict discipline. In England there was a similar protest against the Elizabethan establishment by those who believed the church to be evoked by the Word of God and gathered out of the world into companies of believers: the living, believing, worshiping congregation was the church, and in its life there was the fullness of catholicity; it was free to exercise its own authority in accordance with the Word of God and need not tarry for any magistrate. From such separatist congregations there developed the Independent churches of the Commonwealth period and the modern Congregational Church.

Reaction against an overclericalized medieval world was bound to give prominence to the laity, who during the later middle ages had played an increasingly important role in the Christian world. This tendency continued among the Reformers, for example, the lay magistrate Vadianus (Joachim von Watt) and the lay schoolmaster and preacher Johannes Kessler, in the Swiss city of Sankt Gallen. In the kingdoms and in the cities a swift and effective instrument for Reformation was the "godly prince" and the "godly magistrate." The granting of the *jus reformandi* to the lay authority had its dangers, and the Anabaptists were not the only ones to point them out. The lay authorities on the other

hand were no less apprehensive of a new Protestant clericalism in which new presbyter might be old priest writ large. Calvin, and the Reformed churches after him, sought to safeguard the right of the church to keep its own discipline. Only the Anabaptists repudiated altogether the theory of a Christian commonwealth, sometimes denying that Christians could be magistrates, sometimes contracting out of the political order to form a "pure" society with its own strict discipline.

The Reformers, Luther least of all, did not reckon with the astonishing resilience and power of recovery of the papacy, with those forces of inner renewal, which, beginning in Italy and Spain, produced the Counter-Reformation and which deserve to be considered in their own right as a Catholic Reformation (*see* ROMAN CATHOLIC CHURCH; JESUS, SOCIETY OF). Yet here, too, something was owed to the Reformation itself. It seems unlikely that anything but the immense shock of a grave disaster, a life and death crisis, could have led to the changes which the Western Church had for centuries resisted or postponed.

So far this assessment has been concerned with good religious men, some of them great men, half a dozen of them perhaps spiritual giants. But from the first there were lesser men involved with meaner motives. The ruthless egotists, the cynics, often in high places of commanding power, were able to use and exploit the movement of reform, sometimes to support political ambition, sometimes more excusably to use the wealth of the church as an escape from economic problems which were grave. The over-all picture of the age of the Reformation is therefore infinitely complex and leaves little room for romanticism. None the less, considering the needs of the church, the complexity of the task of reform, the small numbers involved (for no more than 300 Reformers are prominent in history books) there was great creative achievement. New forms of Christian proclamation and truth, new forms of worship and piety, new institutions, new philanthropies were created, above all great new communions of men and women able to endure and grow for centuries, nourished by the unexhausted inheritance received in the first works of the Protestant Reformation.

REFORMATION DAY, the anniversary of the posting of the 95 Theses by Martin Luther on Oct. 31, 1517, thought of as the beginning of the Reformation. At first the European Lutheran territorial churches commemorated the Reformation on various days, among them the anniversary of Luther's birth (Nov. 10), his death (Feb. 18), and the presentation of the Augsburg Confession (June 25). The centennial celebrations of 1617 focused attention on Oct. 31; in the sesquicentennial year 1667 Elector John George II decreed this date as annual Reformation Day in Saxony. German Lutheran and Union territorial churches have come gradually to follow this example and specify Oct. 31 or the Sunday following (or preceding). Among English-speaking Lutherans, the bodies that use the *Lutheran Liturgy* (1948) keep Oct. 31 with an octave; those using the *Service Book and Hymnal* (1958) keep Oct. 31 as Reformation Day and may keep the preceding Sunday as Reformation Sunday. The liturgical colour is red. By custom many North American Protestant churches hold services of evangelical witness on Oct. 31 or the nearest Sunday. (A. C. PN.)

REFORMATORY, a correctional institution for the treatment, training, and social rehabilitation of youthful offenders. Institutions designated as reformatories are of two general types: (1) residential training schools for school-age delinquents; and (2) facilities for the confinement of youthful offenders between the ages of 16 and 25 who have been convicted of criminal acts. These institutions, as their name implies, were originally intended to reform criminal youth. Now frequently referred to by the more descriptive title "correctional training schools," they represent a relatively recent development in the treatment of criminal behaviour. For a survey of philosophies and methods of crime control *see* CRIMINOLOGY: *Correction*. *See* also PRISON; CHILDREN'S COURT; JUVENILE DELINQUENCY.

HISTORY

Youthful offenders as a group were first separated from the general population of prisons and jails in the 18th century. In England, concern for the very young offender was manifested in the efforts of such organizations as the Marine Society, which was formed in 1756 to establish a school for waifs, strays, and the children of convicts; and the Philanthropic Society, which in 1788 opened a school for the children of convicts in London. These were primarily preventive efforts. Early in the 19th century, private reformatories were established under a law which enabled the crown to grant a pardon on condition that the offender place himself in the care of a charitable institution. Under this provision, Farm Colony (Stretton Colony), at Stretton in Warwickshire, was founded in 1817, and could validly claim to be the first reformatory.

Experience with institutions such as Farm Colony was favourable enough to lead to the enactment in 1854 of the first Youthful Offenders Act, which authorized the courts to commit to a reformatory offenders under the age of 16 who had been imprisoned for not less than 14 days. Such offenders would serve terms of not less than two nor more than five years. It is not clear that the regime in effect differed significantly from the repressive discipline of hard labour then prevailing in English prisons, except that some effort was made to maintain a segregation of age groups.

In the United States, experience with reformatories began in 1825 with the New York City House of Refuge, which accepted delinquent and neglected children. Similar institutions were founded in Boston and Philadelphia at about the same time. In France, an especially significant innovation was the agricultural colony of Mettray, founded in 1839. This institution received delinquent children under the age of 16, the "age of discernment" under French law, and kept them in cottages under what was referred to as a "family system."

In 1876 the first significant U.S. contribution to the reformatory movement took place with the establishment of the Elmira (N.Y.) Reformatory. This institution, which early achieved international attention by its annual reports, was historically important because (1) it was the first public reformatory institution for the specialized care of youthful offenders; and (2) it represented public acceptance of the view that, up to a certain age, every criminal might be regarded as potentially a good citizen and that it was the duty of the state to try to effect a cure. Under this principle Elmira Reformatory from the first operated under an indeterminate sentence system, by which release was determined by progress made under the program of training rather than by a judicially established sentence. The regime at Elmira provided for a system of moral, physical, and industrial training followed by parole supervision, all of which was adapted by Sir Evelyn Ruggles-Brise in the organization of the Borstal system (*q.v.*) in 1908 in England.

Early enthusiasm aroused by the reformatory movement was not followed by conspicuous success. Public apathy, uninspired administrative direction, and the lack of professional leadership combined to reduce most reformatories to a condition of bureaucratic stagnation in which, except by the age groups they confined, they were indistinguishable from adult prisons.

MODERN TRENDS

After World War II, the reformatory movement profited from an increase of interest in the behavioural sciences. New correc-

tional training institutions began to emphasize new and varied treatment approaches, including individual and group therapy, therapeutic community plans, establishment of "bridges to the community" by participation of professional and lay persons from the community at large in institutional programs, and family casework and counseling. The older systems, which emphasized military drill, punitive calisthenics, and "cadet officers," have fallen into disrepute, surviving only in places where community interest in correctional treatment is at a low ebb.

Types.—Modern institutions vary in every respect except their assigned task to confine and treat the youthful offender. Students of trends in these institutions have classified them in five significant patterns or types of approach to the common aim of reformation, now generally called resocialization to emphasize the goal of training the individual offender for life in society at large. These patterns are:

Disciplinary.—In the tradition of the conventional reformatory, these institutions emphasize respect for authority, good habits, and conformity to standards. Often the programs of such institutions will follow a military pattern, and there will be stress on staff domination and adherence to strict rules.

Training.—This type of institution seeks to change behaviour patterns through teaching and training. It provides gratifications and incentives to change rather than relying heavily on negative sanctions.

Mixed Goals.—While stressing obedience, this type of institution sets out to emphasize the development of individual controls. The authority of the staff is as unquestioned as in the disciplinary type of institution, but attempts are made to bring about behaviour changes through inmate-staff relationships extending to psychotherapy and other practices diverging from emphasis on strict obedience.

Individual Treatment.—A few institutions have adopted programs emphasizing gratifications and incentives, with individual counseling and psychotherapy stressed as mediums for bringing about personality change. Punishments at such institutions are few and seldom severe.

Milieu Treatment.—In institutions using milieu treatment, there is an attempt to effect change through the development of both individual and social controls. Attention is given not only to the personal problems of clients but also to their preparation for life in the community. Specialized psychiatric and casework personnel are utilized, but their attention is focused on the structure of the institutional community so that all activities are mobilized for treatment effect. Few negative sanctions and many incentives for participation are built into the system.

There is general agreement that whatever kind of program is in force, a system of aftercare is a necessity. The approach to aftercare, usually referred to as parole (*q.v.*), varies from surveillance, to perfunctory case-reporting, to sophisticated counseling relationships based on psychotherapeutic concepts. Many systems in the United States, for example, notably that of the California Youth Authority, integrate a variety of institutions with a flexible parole program designed to capitalize on institutional services.

Examples of Programs.—In the United States there are about 200 youth correctional institutions of all types administered by the 50 states, and the federal system managed by the U.S. Bureau of Prisons. Three experimental programs have received widespread attention as alternatives to lengthy and stigmatizing institutionalization. They are: the Highfields residential training centre in Hopewell, N.J.; the Pinehills project in Provo, Utah; and the Youth Authority's Community Treatment Center in Sacramento and Stockton, Calif. These progressive programs emphasize individualized treatment of short duration, aimed at inducing adherence to acceptable norms through peer-group influences as well as staff treatment. Highfields treatment is designed for groups of 20 youths living together for four months and undergoing a simple program of work and "guided group interaction." Pinehills provides nonresidential care consisting of after-school work on civic improvement projects followed by daily sessions of group counseling. California's community treatment relies on caseloads of 10, in which counselors working with individualized treatment plans supervise youthful offenders in the community with no institutional confinement beyond a brief diagnostic study at a reception centre. All three of these programs are based on well-developed behavioural theory, and promise to reduce both the human and economic cost of correctional care.

English reformatory services have traditionally been divided between "approved schools" for the school-age delinquent, and the Borstal system for the older boy or girl. Dissatisfaction with these long-term residential services as costly and inappropriately severe for the delinquent in minor difficulties has resulted in a third variety of institution, the detention centre. These small institutions receive boys for periods of three to six months and administer a vigorous program of work and athletics. While there has been much criticism by psychiatrists and social workers of the indiscriminate nature of the detention centre approach, in which no attempt is made to diagnose, preliminary studies of their statistical success suggest that they compare well with the results achieved by Borstals and approved schools with somewhat similar boys.

Approved schools are maintained for delinquent children up to early adolesence when judged in need of long-term removal from undesirable surroundings. There are about 120 such schools with a total population of approximately 10,000. Many are maintained by private philanthropic foundations to which the government contributes a per capita rate for each child committed. Others are entirely maintained by the government. Because of the large number of these schools, it is possible to provide for specialized services through the use of strategically located schools for diagnosis and classification. Several schools have made innovations in treatment approaches, notably Aycliff, which has stressed the use of reinforcement of behaviour through incentive systems, and the Park School, in Surrey, which has used social casework methods in attempts to involve family members in the treatment programs of its residents.

The approved school model has been widely copied in Scandinavia, where systems of small residential schools have been established. At the Children's Village (Barnbyn Skå) near Stockholm, a therapeutic-community type of treatment has been pioneered under psychiatric leadership. An unusual feature of this school is its coeducational organization, despite the highly disturbed condition of most of its population. In Denmark, an unusual feature of the reformatory system is its incorporation in a larger system of child welfare schools intended for problem children whether delinquent or not. In the Netherlands, experiments have been successfully carried out in the management of residential care for delinquent boys in a vocational training institution attended also by nondelinquent day-school boys. French reformatories have continued the tradition of family cottages managed by specially trained social workers. Care is given to maintain continuity of treatment relationships so that as little interference as possible occurs in the parental relationship of house-parents to children.

In the Soviet Union, interest in the exploitation of group influences to change and maintain behaviour patterns has been continuous since the Revolution. This interest has been directed not only at the rehabilitation, or resocialization, of delinquents but also at inducting young people into the normal processes of industrial, agricultural, and community life. The leadership of Anton S. Makarenko, a gifted educator of the early postrevolutionary era, was aimed at developing a sense of community among the homeless children of that chaotic period. Observing the salutary effect on the individual of participation in the group solution of practical problems, he advocated the development of corrective labour colonies for youth in which remedial education would be combined with work projects in which all would join.

Soviet authorities minimize the incidence of delinquency in the U.S.S.R., but many residential schools have been established in which delinquent and nondelinquent children are housed and taught together. Little attention is given to aftercare, as it is known in Western countries, because of continuities which are established between schools and workers' collectives.

Summary.—The reformatory movement made significant contributions to modern penology with the introduction of indeterminate sentences and separate institutions for youthful offenders

based on the premise that most youths are capable of resocialization. The early reformatories, however, did not fulfill the enthusiastic promise responsible for their establishment, and many still resemble junior prisons, with rigid discipline and little treatment. After World War II, however, more and more correctional training programs for youthful offenders were aimed at resocialization through remedial academic and vocational education, reinforced by sophisticated uses of group influences and, where indicated, psychiatric treatment. The experience of these institutions was beginning to show that for many classes of youthful offenders, long terms of confinement could be drastically shortened, if not entirely eliminated. Thus, with the development of correctional training schools, the reformatory movement had virtually abandoned the older term "reformatory," with which it began, and seemed to be on the way to abolishing the prisonlike institution it used to describe.

REFORMED CHURCHES are those European churches which during the Reformation undertook to reform their faith and life, as they declared, "according to the Word of God," under the leadership of such men as Huldreich Zwingli, Martin Bucer, John Oecolampadius, Guillaume Farel, John Calvin, and Heinrich Bullinger. The Evangelical (or Protestant) Reformation of the 16th century was a many-sided answer to a complex and long-standing set of problems. (*See* REFORMATION.) Consequently, it was inevitable that reform, when it came, was of several varieties. The Reformed churches represent one general type or pattern of reform which emerged in this period. The pattern first took form in Strasbourg and in Zürich, later spreading over much of Switzerland, southern Germany, France, the Netherlands, Hungary, and the British Isles, with lesser influences elsewhere. These churches are now worldwide in distribution.

Various names are used for the Reformed group of churches: Reformed, Presbyterian, and Calvinistic. The name Reformed is that most commonly used on the European continent. Originally, however, all the Reformation churches used this name (or Evangelical) to distinguish themselves from the "unreformed" or unchanged Roman Church. After the great controversy among these churches over the Lord's Supper (after 1529) the followers of Luther began to use the name Lutheran as a specific name, and the name Reformed became widely used of the other Reformation churches (including the Church of England in the 16th century). The name Presbyterian, properly, refers to the form of church polity used by the Reformed churches. Eventually, however, this term came to be used of all the Reformed churches of British background; hence these are discussed separately in the article PRESBYTERIANISM. The name Calvinistic has become almost synonymous with Reformed and Presbyterian, though John Calvin (*q.v.*) was of the second generation of leaders of these churches rather than the first. Coming after the first great reformers, he systematized, adapted, and improved upon their work. He was the greatest intellect among these early leaders and the most influential upon subsequent generations.

HISTORY

Beginnings in Christian Humanism

The first phase of the development of that pattern of reformation typical of the Reformed churches occurred in the German-speaking areas of Switzerland and in southern Germany. Here, in a region deeply influenced by the newer intellectual currents of humanism, growing urban culture, and freer movements of people, trade, and ideas, the demand for reformation assumed a distinct character. The early leaders were the so-called Christian humanists, Desiderius Erasmus, Johann Reuchlin, Jacob Wimpfeling, Beatus Rhenanus, and others. Impatient of the obscurantism of the recent past, bitterly critical of the monastic orders, often anticlerical and antihierarchical, the humanists called for a return to a simple Bible-centred piety and for repudiation of emphasis on sacramentalism, institutional religion, and technical dogma. Renaissance humanism had sought to reinvigorate European intellectual life by advocating a "return to the sources"; *i.e.*, to the great classics of ancient Greece and Rome. The Christian humanists urged a return to the sources of Christianity (*i.e.*, to the Bible and to the early Church Fathers) as a means of recapturing the true nature and spirit of Christianity. Here they found a simple "philosophy of Christ" which taught that Christianity was a way of life, nurtured and furthered by education and by earnest ethical endeavour.

Almost every early Reformed leader in Switzerland and in southern Germany—Zwingli in Zürich, Oecolampadius in Basel, Bucer and Wolfgang Capito in Strasbourg, Franz Lambert in Marburg, and Farel in Bern (and elsewhere later)—had begun as a Christian humanist. However, the frank, nontraditional study of the Bible and the early Church Fathers which these men advocated made many of them dissatisfied with humanism's avoidance of serious theological issues such as the problem of sin or the nature of grace. Luther's break with the Roman faith (1517 to 1520 especially) gave to these men's thinking a new sense of direction and of urgency. Yet, as they and Luther recognized, they were not dependent upon Luther nor were they his disciples. Rather they developed a pattern of reform from their own backgrounds and studies. Their desire to "return to the sources" led them to try to restore insofar as possible the primitive patterns of church life and institutions. Like many humanists they regarded the original form of an idea or institution as the best and most ideal. Therefore, the New Testament church was the church closest to the divine plan and intention, and its pattern ought to be the standard by which all subsequent changes and developments were judged. This return to the sources led to a much more radical reform than in Lutheranism or in Anglicanism and to a sweeping away of much more of traditional Roman views and usages.

Other marked continuations of humanistic concerns were openness to cultural change and great emphasis upon ethical, political, and intellectual problems. A change, however, came in that these concerns were now dealt with more and more upon the basis of a Pauline-Augustinian view of sin, grace, etc. In general, these reformers, especially Bucer, looked for the renewal of the whole of society—religious, moral, intellectual, political—by a rebirth through divine grace which would in some measure restore the original goodness of the whole of God's creation. Concern for these aspects of human life, therefore, was not regarded as secular or nonreligious. Rather, the healing and renewal of society in general was a vital part of redemption.

Switzerland

Origins.—Zürich, a city already conditioned by humanism, broke from Roman Catholicism in 1522 in a manner that was to become virtually standard for all the Swiss cities, or cantons, and that was to have far-reaching consequences. The Swiss, in general, had been loyal to the papacy, yet episcopal authority was vague in many cantons for a variety of reasons. Moreover, the Swiss had developed a remarkable federation of their cantons, within each of which a democratically elected government was in almost complete control of internal affairs. When controversy over the preaching of Zwingli and his colleagues broke out in 1522, the Council of Zürich assumed jurisdiction on the grounds that as the elected government it was the expression of the will of the people. Zwingli and his colleagues demanded a public disputation between the Roman priests and the reforming party, and that thereafter the Council, in the name of the people, should determine the theological character of the church in Zürich. Over a three-year period, 1522–25, the Council of Zürich accepted a fully Protestant church

reform. Basel did likewise in 1525 under the leadership of Oecolampadius, Capito, and Farel. Bern, the most powerful of all the cantons, followed suit in 1528. Sankt Gallen, Biel, and others also made the change in the same manner.

Opposition from those cantons which remained Roman Catholic grew, and Zürich and Bern led in the formation of the Christian Civic League in defense of the Evangelical Reformation. Eventually even German cities such as Strasbourg joined, and Hesse and Württemberg showed interest. The Roman forces now joined in the Christian Union. In the two wars that followed (1529 and 1531), the Evangelical forces were finally defeated, Zwingli was killed, and the Evangelical advance was all but permanently halted. Moreover, political leadership in Swiss Protestantism passed from Zürich to Bern. Evangelical and Roman groups agreed to recognize the right of each other to exist. Heinrich Bullinger succeeded Zwingli as leader in the church at Zürich. (*See* also SWITZERLAND: *History;* ZWINGLI, HULDREICH.)

Meanwhile the controversy over the Lord's Supper had broken the Swiss reformers away (after 1529) from the German reformers led by Luther and had brought the Strasbourg reformers led by Bucer into the role of unsuccessful mediators (*see* BUCER, MARTIN). After Zwingli's death Bullinger and the other Swiss reformers came to an understanding with Bucer, and even with Philipp Melanchthon, but they could not do so with Luther. Henceforth no one theological mind dominated the Reformation of the Swiss-German Rhineland, and a great area of mutual agreement gradually arose. Bern took over and advanced the policy laid out by Zürich of forwarding the Reformation by open debate and elections. In the furtherance of this policy Bern had as agents a number of Evangelical preachers—of whom Farel was one of the leaders—who went everywhere, preaching and debating in Roman Catholic areas. So successful were their efforts that in 1532 it was possible to call a synod of 230 Evangelical preachers at Bern. Bucer was present as an adviser.

Farel turned his attention to Geneva in 1532 but found progress very slow and difficult. Only after riots and threats of force by both Catholic and Protestant cantons did Geneva finally agree to hold a public disputation in 1534. Catholic troops led by the prince-bishop besieged Geneva. Bern, by coming into the war, saved Geneva and crushed the forces of the ruling House of Savoy. This brought Geneva somewhat under Bern's tutelage, with Farel as the religious leader. He was, however, unable to get an Evangelical church life established in any real measure the first year.

Farel saved the situation by persuading John Calvin, a young French Evangelical refugee, to become his assistant. Calvin had, in addition to great theological and pastoral gifts, unusual organizing abilities. Geneva had become Evangelical for political reasons, and it wished to do as Bern, Zürich, and other Swiss cities had—that is, control and use the church. Calvin and the other Genevan pastors demanded independence for the church in religious matters and the right to criticize on religious grounds the acts of the government and the moral life of the city. The church, however, was to have no authority in civil matters. After three years Farel and Calvin were dismissed by the civil authorities because of this clash of ideas (1538). Calvin became a pastor in Strasbourg. In 1541 he returned to Geneva as pastor and teacher.

Genevan Reform.—Work was now begun on the reforming of the church in Geneva. Calvin followed many of the ideas of the older reformers, including Luther, but with some notable adaptations and additions which soon came to be characteristic in a general way of most of the Reformed churches. One of the major causes of the Reformation as a whole had been the urgent demand for moral renewal. Humanist, Lutheran, and Reformed leaders all sought this moral renewal in various ways. Zwingli and Bucer had made some slight progress in the matter, but Calvin instituted a system of church discipline more far-reaching than that of any other Protestant community. In spirit and content most of these "blue laws" were medieval, and many had been enacted before Calvin's time, but their rigorous enforcement on all persons of every class was new. This so-called Genevan theocracy was not civil rule by ministers; no minister could hold civil office in Geneva. But the ministers as interpreters of the biblical law exercised a powerful influence on legislators, judges, and other civil officers. Moreover, Calvin had taken a doctorate in law in his youth, and in general the ministers were the best-educated men in the city. Also, excommunication from the church was regarded as a major disgrace, if not calamity. These factors gave the ministers great power in the church courts, which were composed of ministers and elders from the congregation. Yet the personal force of Calvin, Theodore Beza, and other ministers was the actual power behind this theocracy. More than ever before, the Reformed churches under Calvin's influence emphasized the ethical character of the Reformation.

The Church and Political Authority.—This emphasis led in turn to two other involvements which affected all the other Reformed churches: the problem of church and state and that of the nature of political authority. Europe had had centuries of conflict between the papacy and the various kings and emperors, a conflict that had also been a major cause of the Reformation. Since the papacy fought all aspects of the Protestant Reformation, no such movement succeeded anywhere in Europe without the aid of the civil powers. Inevitably this had meant that the civil authorities came into actual control of the church within their domains. This control was sometimes exercised paternalistically or indirectly; at other times the church was made a tool of civil policy. But, as such, the control was accepted by all the early reformers as the only alternative to control by the papacy.

Calvin sought a third possibility, a church made up of all the inhabitants of the country, a church protected by the civil government and receiving legal sanction for its basic constitutional documents from the civil authorities. This constitution, he urged, should allow the church to choose its own officers, including its pastors; to constitute its own strictly ecclesiastical courts; and to administer its own affairs under its constitution within and through its own officers and courts. This qualified separation of church and state was severely controverted in Geneva and even among other Reformed churches for a time (*see* ERASTUS, THOMAS). Gradually it became typical of the Reformed churches and was broadened in the direction of the ideal of a church wholly free of the state. Even the relative freedom won for the church from the state by Calvin meant that the ideals, policies, doctrines, etc., of the Reformed churches could be spread internationally with greater freedom because their acceptance in any given nation implied no negotiations with, or tie to, the Genevan government or the Swiss federation.

In the bitter social and political struggles that took place in many nations of Europe in the 16th century, as well as in the severe religious struggles between Roman and Evangelical, Lutheran and Reformed, Evangelical and Anabaptist, etc., the question of the nature of political authority over a people was debated repeatedly. Calvin adopted and greatly advanced the notions of popular sovereignty, a written fundamental law or constitution, government resting upon a contract between people and rulers, government by representatives of the people, and the right of the people to constitutional resistance if a ruler violated his contract to rule according to the constitution. The Reformed churches, the Huguenots (*q.v.*) especially (and the Presbyterians in England and Scotland), made these theories their major artillery against the divine-right monarchies of Europe. Men such as John Locke made them the basis of standard British and American political theory apart from their earlier religious basis.

Civil and religious authorities worked well together in Geneva for a time. However, when the church attempted to discipline members of the upper, ruling class, trouble came from the civil authorities. Also, Calvin's insistence upon making Geneva a centre for Evangelical refugees caused great resentment among the "old Genevese" party. The group in the city for whom the religious change from Catholicism to Evangelicalism had been essentially a part of the move for civic independence made common cause with those who resented the whole religious reform. In 1553 Calvin's cause seemed defeated.

Two years later the civil authorities gave up all control over the internal life of the church but still held out on the issue of the refugees. When the leaders of the opposition to Calvin were found to be in secret negotiations with the French king their whole

cause collapsed. Calvin was then free to settle church affairs, found the University of Geneva, train refugee ministers for service all over Europe, and make Geneva the Evangelical centre of the continent. He held no office other than that of pastor of the church, though his influence was enormous. Gradually, leadership of the various Reformed churches passed to Geneva. Calvin died in 1564, and his successor, Theodore Beza, was the acknowledged leader of French Protestantism. Under Beza's successors Genevan leadership declined, and by the 18th century the city was dominated by the Enlightenment. German Switzerland came to greater prominence. French Reformed leadership was never again great.

Modern Switzerland.—During the Reformation most Swiss cantons had their own state churches. This pattern has never been dropped. During the 20th century most of the churches were disestablished in greater or lesser measure, without losing their character of national churches. The presbyterian form of government in general prevails in these churches. No particular creed is used by any of them, though, in general, they follow the Reformed tradition in thought and life.

Switzerland has become the international centre of world Protestantism, and the Reformed churches have contributed much to this ecumenical work. During the two world wars the Swiss churches did much to hold the Evangelical churches together. In 1948 the Swiss Reformed churches formed a federation which included roughly three-fifths of the population of Switzerland. By the 1960s this federation had nearly 3,000,000 members.

Germany

Strasbourg.—Matthew Zell, who had been influenced by Zwingli, began preaching Evangelical doctrine in Strasbourg as early as 1521. Soon he was joined by Wolfgang Capito from Basel, and others. Martin Bucer, who had become an Erasmian reformer, met Luther in 1518 and became an Evangelical. In 1524 he went to Strasbourg and shortly was made pastor. Subject now to influences from Zürich, Basel, and France, Bucer gradually moved away from Luther. At the Diet of Augsburg (1530) he led a small group of Germans and others who sought a middle ground between Luther's and Zwingli's groups. From then on he followed a policy of mediation first between the various reforming groups and then between the reforming groups and Rome. Melanchthon, and Calvin at times, aided him in these moves. When the Augsburg *Interim* was forced on Germany (1547–48), Strasbourg was compelled to become Roman Catholic, and the Reformed leaders were exiled. Bucer and some others went to England, still others went to Switzerland. When the *Interim* was lifted Strasbourg became exclusively Lutheran until 1789. (*See* also Germany: *History.*)

The course of the Reformed system in Strasbourg, therefore, was limited to the period 1521–48. However, during that period some decisive events took place. Strasbourg became the German centre of Swiss Reformation thought. All down the Rhine Valley Swiss-Strasbourg influences moved, even into the Netherlands. John Calvin found refuge in Strasbourg during 1538–41 and both made and received lasting contributions. English Puritans before, during, and after the "Marian exile" were permanently affected by the theology of the Rhineland, and Bucer eventually went to England. Without Strasbourg's role as a channel, the influence of Zürich, Basel, and Geneva upon the outside world might have been small, and the Reformed churches might have been limited to Switzerland and France.

Reformed and Lutheran.—In many ways it was the elector Frederick III of the Palatinate who gave the German Reformed Church its great opportunity. During the later years of Melanchthon's life, and for some time thereafter, grievous controversy raged among Lutherans between an ultra-Lutheran faction and a more moderate group of Melanchthon's followers. The violence of the controversy turned many minds toward Calvinism, or the Reformed views. Frederick made Heidelberg University a centre of Reformed thought, bringing to it men such as Zacharias Ursinus and Caspar Olevianus. Ursinus had been first a Melanchthonian Lutheran and had later come under Peter Martyr (Vermigli) and Farel. Frederick commissioned these men to draft a constitution for the Palatinate churches which would more nearly express the Reformed views. The Heidelberg Catechism (*q.v.*) which they drew up (1563) quickly became the catechism of all the Reformed churches. It was attacked fiercely by the ultra-Lutherans, and soon it was being asserted that those who held its views had no right to toleration under the terms laid down in the Peace of Augsburg (1555). Frederick fought the issue to a successful conclusion at the Diet of Augsburg (1566), thus gaining a clear-cut admission that the Reformed churches had the right to exist parallel to the Lutheran churches allowed by the diet of 1555.

Despite temporary or local losses the Reformed churches spread down the Rhine. The Wetterau counties became Reformed, and at Herborn a famous Reformed university was founded. Emden and Bremen also became Reformed, then Brandenburg (1613) with its capital, Berlin. Other smaller areas scattered over the German states were also brought into the Reformed church.

The Thirty Years' War brought the Reformed territories almost to ruin, and at the Peace of Prague (1635) the Reformed groups were so wholly betrayed that the war was resumed. The Peace of Westphalia (1648) explicitly recognized the Reformed churches and restored the lands of the Reformed nobles. It also recognized Switzerland's independence of the empire. The revocation of the Edict of Nantes in 1685 brought into Germany 60,000 Huguenot refugees who greatly strengthened the Reformed churches. During this same period the French ravaged the Palatinate and greatly reduced the Reformed churches, which were saved only by the intervention of Brandenburg. Yet a century of serious hardship (until 1802) was their fate.

Beginning in 1817, Prussia united, by three stages, the Reformed and Lutheran churches in its territories. The first stage was federation, the second (1830) a common liturgy, the third (1834) allowed each congregation the right of using whichever creed and liturgy it wished (Reformed or Lutheran). The territories in which the Reformed groups had their greatest strength were Brandenburg, Prussia, Pomerania, Silesia, Posen, Westphalia, and the Rhine provinces. Those provinces which joined Prussia after 1817 —Hanover, Nassau, and electoral Hesse—were not compelled to unite their churches, although Nassau had done so previously at its own order. Small local unions were made in these areas, however. Nonunion Reformed churches remained in Bremen, Lippe, Alsace-Lorraine, Lower Saxony, and elsewhere. Generally speaking the Reformed tradition was overshadowed by the Lutheran as the union continued. In 1861 Reformed leaders began to revive, but within the various union agreements, a greater appreciation for the Reformed tradition and ethic. Inner mission work among the poor and the sick also was pushed, as were foreign missions, youth work, and other social activities. A vigorous literature on the Reformed ideals began to appear.

20th Century.—World War I and the years immediately following wrought havoc in all German churches. Old cultural patterns disappeared and an industrialized, secular society emerged. The close connections of all the churches with the German state had become a hindrance, and the disestablishment which came under the Weimar Republic was in itself good. It came, however, when the churches could least afford the financial and other losses entailed. Beginning in 1918–21 a vigorous theological renewal took place in Germany. The Reformed Federation, led by August Lang, brought Karl Barth to Göttingen University, where he quickly became the leading Reformed theologian of modern times.

As the Nazi regime took over, Barth and Otto Weber, of the Reformed Federation, became leaders in the struggle of the German churches against Hitler and neopaganism. (*See* German Confessing Church.) World War II brought serious losses to the Reformed churches. Those regions of Germany where they were strongest fell into the Russian zone of occupation. In Hesse, the Ruhr, and other regions of West Germany they recovered slowly after the war, aided by U.S. Presbyterian and Reformed churches.

The Reformed Federation in the 1960s had about 2,500,000 members. The Evangelical-Reformed Church in northwest Germany had about 230,000.

During the height of Germany's power, German Reformed

groups spread out over a large part of Europe and also into Russia. Sizable churches were established in Austria (Vienna), Yugoslavia, and Slovakia, smaller bodies among German settlers in Russia, Lithuania, and Latvia. In the territories which were alternately Polish and German in the 19th and 20th centuries there were large Reformed groups. The status of these groups deteriorated seriously after World War II.

The Netherlands

Reforming interest emerged in the Netherlands early in the Reformation era. Erasmus did much of his best work at Rotterdam. Moreover, the Brethren of the Common Life (*q.v.*) and other mystical groups had been active in the Low Countries. Erasmian and mystical types of reform were soon followed by Zwinglian and Lutheran influences. Communications, and other interests also, bound the Rhineland and the Netherlands together. Hence the Swiss-Rhineland type of reform came to predominate. The emperor Charles V instituted the Inquisition against the Reformation in the Netherlands as early as 1522. The struggle for freedom from Spain was begun by the Netherlands as a protest in demand of greater liberties, including religious, within Charles's empire. Eventually, Holland became free, and the Reformed church was established. (*See* Netherlands, The: *History.*) During this long struggle the religious situation had become clarified. The leaders in the war for freedom had been deeply influenced by French Huguenot-Calvinist political and religious thought. Lutheran and Erasmian ideas had given way to a theology blended from Rhineland, Genevan Calvinist, and French Huguenot influences, and ideas drawn from the younger Jan Laski's work. The Belgic Confession (*Confessio Belgica*), written in 1561, became the standard creed. The church was not a national church. The Netherlands comprised a federation of states with great local autonomy, and each state had its own church over which the local authorities had almost complete powers. National synods were provided for but were seldom allowed by the various states.

Arminianism.—Civic peace had scarcely been achieved before a theological revolution took place in the Dutch church. Calvinists, in their controversies with Lutherans and Catholics, had carried their philosophical development of Calvin's religious view of predestination (which he shared with Luther) to great lengths. Some Reformed thinkers began to raise objections, among them the Dutch theologian Jacobus Arminius (*q.v.*). Other issues were also involved, especially Dutch political issues. The leader of the ultra-predestinarian Calvinists in the Dutch Reformed churches was Franciscus Gomarus. To solve the issue, a synod of representatives of Reformed churches in all countries was called by the civil authorities. James I of England took special interest in the synod and sent representatives from the Church of England. The synod met at Dort in 1618–19, condemned Arminius' mild views, rejected Gomarus' extreme views, and stated in classic form the hyper-Calvinistic view which had become the badge of the Dutch Calvinists in their polemics with other theologians. The term Arminianism became a very broad designation in Europe for any deviation from any essential aspect of Calvinistic orthodoxy, whether or not connected with Arminius' followers or the original points of controversy. (*See* also Arminianism; Dort, Synod of.)

19th–20th Centuries.—In 1798 the Dutch Reformed Church was disestablished, but it remained partly under government control. In 1816 King William I reorganized the church and renamed it Netherlands Reformed Church. Conflict over church organization and religious orthodoxy led to a separation of some conservative elements in 1834, most of these being united in 1869 in the Christian Reformed Church. In 1886 a second exodus of conservatives from the Netherlands Reformed Church was led by Abraham Kuyper (*q.v.*). This group united with the majority of the Christian Reformed Church in 1892 to form the Reformed Churches in the Netherlands, a strongly evangelical church that remains the second largest Protestant church in the Netherlands.

In 1926 a group under Johannes Gerardus Geelkerken was expelled from this church for doctrinal reasons; they united with the Netherlands Reformed Church in 1946. A more serious schism occurred in the Reformed Churches in the Netherlands in 1944, when a large group of zealous conservatives separated to form the Reformed Churches in the Netherlands (Freed).

Other Reformed churches, consisting of very conservative groups that did not go along with the unions of 1869 and 1892, include the Christian Reformed Churches, the Reformed Congregations, and the Old-Reformed Congregations, all with membership of less than 100,000. The Arminian group that was expelled from the Dutch Reformed Church in 1619 survives as the Remonstrant Brotherhood.

The Netherlands Reformed Church had about 3,000,000 members in the mid-1960s, the Reformed Churches in the Netherlands about 800,000.

Former Dutch Colonial Areas.—The Dutch churches followed the colonial expansion of the country. In South Africa they became the principal Christian churches. This, together with the Dutch tendency toward political parties following confessional lines, gave these churches a very great responsibility. With few exceptions, the Reformed churches in South Africa reflect the views of the Afrikaners; the post-World War II premier D. F. Malan, who led the campaign for the total segregation of the population and areas of South Africa on racial and colour lines, was an ordained Reformed minister. Most Reformed churchmen, and the Reformed churches officially, approved his policy and continued to support his successors.

Controversy over doctrinal issues divided the church in South Africa as well as in the Netherlands. Six distinct bodies in the 1960s claimed an aggregate (white) membership of approximately 1,350,000. A "mission church" for nonwhite missionary converts claimed a membership of about 150,000.

Indonesia, prior to its independence, had a Dutch church of about 300,000 adherents. The readjustments after independence seriously weakened it.

Other European Countries

France.—From the beginning, the Reformation made slow progress in France. Yet reforming movements within the Roman Catholic Church had been early in appearing. Before Luther had emerged as a Reformer French humanists had created much interest in biblical studies and had aroused a concern for a purer type of Christianity. In time Margaret of Angoulême, King Francis I's sister, became the centre of a humanistic group known as the group of Meaux, which, while it never broke with the Roman church and never became outright Evangelical, created great interest in reform. Also, members of it, such as Jacques Lefèvre d'Étaples, contributed much by their writings to biblical and theological studies which the Evangelicals could and did use. Again, several of the group—among them Nicholas Cop and Guillaume Farel—left it and became professed Evangelicals. But it was not until 1555 that any real attempt was made to organize Evangelical congregations in France.

Calvin, Farel, and Beza, all Frenchmen active in Geneva, had maintained a deep interest in the French reform movement. Hundreds of students had been sent to France from Geneva on evangelical missions. By 1560 it was estimated that there were about 300,000 Evangelicals in France and at least 49 organized congregations. In general these Reformed churches (all Protestants, Reformed and Lutheran, were called Huguenots) followed Calvin's views, yet on many critical matters they made changes. In a long series of civil wars, beginning in 1562, they alternately gained and lost.

Peace finally came when the Huguenot leader Henry of Navarre became king as Henry IV and abjured Protestantism. This satisfied the Roman Catholic faction, and Henry in 1598 promulgated the Edict of Nantes, which guaranteed the Huguenots virtual freedom of religion. (*See* Nantes, Edict of.) During this era of strife had occurred the greatest horror of the Reformation, the massacre of 20,000–50,000 Huguenots throughout France beginning on St. Bartholomew's Day, 1572 (*see* Saint Bartholomew's Day, Massacre of).

The French Reformed churches recovered in great measure from these frightful persecutions after 1598. But the Edict of Nantes was revoked by Louis XIV in 1685. Untold sufferings pre-

ceded and succeeded this act, and despite laws against emigration over a quarter of a million Huguenots fled—to Germany, Holland, England, Switzerland, and the New World. Those who remained persisted as a virtual underground movement and did not regain their full rights until the Revolution of 1789.

Since the Revolution France as a nation has been indifferent to all religions. The French Reformed churches have grown slowly under great handicaps. (*See* also HUGUENOTS.)

The Reformed Church of France in the 1960s had about 195,000 members, the Reformed Church in Alsace-Lorraine about 22,000; Evangelical Reformed churches outside the united body numbered 50 congregations.

Hungary.—The influence of the Reformation was felt early in Hungary. A synod at Erdod adopted the Augsburg Confession in 1545, and by 1567 the works of Farel and Calvin had become so well known that the Synod of Debrecen adopted the Heidelberg Catechism and the Second Helvetic Confession, thus becoming a Reformed church. Except for minor reverses the Evangelicals made progress in Hungary until 1655, when Leopold I came to the throne. The Counter-Reformation era was one of severe persecution for all Evangelicals, and not until the emperor Joseph II promulgated the Edict of Toleration in 1781 did respite come. Within the old empire the Reformed church was of two wings, the Magyar (the larger) and the German; the Magyars spread rather widely through the empire, carrying their church with them. Theologically the Reformed churches were much influenced by German scholarship. Within the empire they built up a large system of schools, elementary through university, and did much for Hungarian cultural life.

The Peace of Versailles following World War I shattered the Hungarian Reformed Church. Only half of the church remained within the new nation of Hungary; the other half was represented by minority groups in unfriendly or even hostile countries. The largest segment, 780,000 in Rumania, suffered grievously for both religious and cultural reasons. The 210,000 in Slovakia suffered less, and the small group of 40,000 in Yugoslavia led a precarious existence. World War II defeated all hopes of reuniting the Magyar people and their church.

Czechoslovakia.—The Reformed churches of Czechoslovakia are, like the nation itself, of varied origins. The Czech Reformed body is the Evangelical Church of Bohemian Brethren. The Slovak Reformed body is a wing of the Hungarian Magyar Reformed family.

John Huss's attempt at reforming the church in Bohemia ended at the stake in 1415. His followers were crushed in 1434, but underground the cause persisted. During the 16th-century reforming movement in general, the Bohemian Brethren emerged again to flourish for a brief period. In 1547 they were again suppressed, and the Jesuits were given charge of religious affairs in Bohemia. A Bohemian revolt in 1618 began the Thirty Years' War in Europe, and thereafter the House of Habsburg and the Counter-Reformation held unchallenged sway in Bohemia. Thousands of Evangelicals—nearly a quarter of the urban population and the nobility—fled the country, patriot and Evangelical leaders were executed. Not until 1781 (Joseph II's Edict of Toleration) were Evangelical groups again tolerated in Bohemia, and then only bodies holding either of the two German Protestant symbols (Augsburg or Heidelberg). The old native Bohemian church was still banned, though it remained in existence underground. Moreover, the cause of Czech independence and that of the Bohemian church became intertwined.

When the nation of Czechoslovakia was created by the Peace of Versailles, the Evangelical Church of Czech Brethren was freed, to become the leading Protestant church in the nation. Its leadership in theological education, social work, etc., was marked. During the crises preceding World War II Czech patriotism and the Bohemian Brethren again made common cause. When the German Army seized Czechoslovakia the consequences for this Reformed church were severe. Many of its leaders, Joseph Hromadka among them, had to flee. The postwar Communist government presented the church with a new crisis. It had been predominantly middle and upper class, with no great hold on the classes now influenced by Communism. Under the leadership of Hromadka the church made great efforts to come to an understanding with the government and with the proletariat in order to overcome its previous social stratification and isolation. (*See* also BOHEMIA: *History;* HUSSITES; MORAVIAN CHURCH.)

Other Countries.—Small Reformed churches, often only a few scattered congregations, are found in Austria, Lithuania, Latvia, Poland, Belgium, the Scandinavian countries, Greece, Spain, and Portugal. The ancient Waldensian churches of Italy (*see* WALDENSES), together with their branches in Uruguay and Paraguay, have also come within the orbit of the Reformed churches, though preserving their own character.

UNITED STATES

The Reformed churches have been represented in North America largely through their English-speaking wing, the Presbyterians. However, some continental European Reformed churches have been established by immigration into the United States; none has done so in Canada or Mexico.

The Reformed Church in America.—The first Reformed church of continental European background to establish itself in North America was the Dutch Reformed Church, which during the period of Dutch sovereignty over New Netherland was the established church of the colony. When the English seized the colony they gave assurances that the Dutch Reformed Church would be allowed freedom from English control and that it would be permitted to continue under the ecclesiastical jurisdiction of the classis (Church governing body) of Amsterdam. Under this control the church grew slowly in New York, Long Island, and New Jersey. In 1679 the classis of Amsterdam allowed a colonial classis to form, but restricted its powers severely.

Early in the 18th century new movements came: colonial self-consciousness, declining interest in things Dutch, the Great Awakening revival of religion, and increasing interest in cooperation with other churches, especially the Presbyterians. The Dutch church became split into two factions, one, a colonial party, desiring greater freedom from the classis of Amsterdam, free use of the English language in worship, a local college for the training of ministers, and support of revivals in the churches; the other, a conservative Dutch party, wishing to retain Dutch authority and influence—Netherlands-trained pastors, Dutch language in worship, etc. The colonial party soon predominated. In 1770 it founded Queen's College, later Rutgers University, at New Brunswick, N.J. The two factions reunited in 1771 under a plan which left ultimate authority in Holland but gave great local autonomy. After the Revolutionary War the church became wholly independent under a new constitution drafted 1784–92; by 1820 the Dutch language had ceased to be used. The name Reformed Protestant Dutch Church was changed in 1867 to Reformed Church in America.

A large migration of Dutch people into the United States about the middle of the 19th century added greatly to the church. Most of these settled in Michigan and other midwestern areas, giving the church, therefore, two integrally related though rather distinct groups centred in New York and New Jersey and in Michigan and Iowa. The older, eastern section of the church has been much more severed from its ethnic origins and is much less conservative theologically than the newer, midwestern section.

Several attempts at union between the Reformed Church in America and other Reformed or Presbyterian bodies in the United States have been made since the early 19th century, none successfully. The church in the 1960s had about 230,000 members.

The Christian Reformed Church.—In 1822 a small group withdrew from the Reformed Protestant Dutch Church and formed the True Reformed Dutch Church. In 1857 another schism from the parent body formed the True Holland Reformed Church. Further immigrations from the Netherlands and a further schism from the parent body increased the new denominations. In 1890 they united to form the Christian Reformed Church. This church, which adheres to the Heidelberg Catechism, the Belgic Confession, and the Canons of Dort, had about 250,000 members in the 1960s.

Evangelical and Reformed Church.—This body was formed

in 1934 by the union of the (German) Reformed Church in the United States and the Evangelical (Lutheran) Synod of North America. In 1957 it entered into a merger with the Congregational Christian Churches to form the United Church of Christ; the constitution of this new body came into force in 1961. (*See* CONGREGATIONALISM: *History: United States.*)

Early in the 18th century Palatinate Germans, Reformed in confessional allegiance, began coming into the American colonies largely as refugees from the wars between France and Germany. They settled in Pennsylvania and in the Valley of Virginia for the most part. Due to the turmoil in the Palatinate their own home church could not help them, but they were aided by the Reformed Church of Holland and under Michael Schlatter, who had been sent from Holland, formed a coetus, or governing church body, in 1747. The Presbyterians also aided them in various ways. Attempts to unite them with either the Dutch Reformed Church or the Presbyterians failed, largely for cultural reasons. After the Revolutionary War, the German Reformed groups in Pennsylvania and Virginia formed a synod of the German Reformed Church in the United States (1793).

New immigrants of German Reformed persuasion came into the United States in the 19th century. Until 1863 these new groups formed separate and distinct synods only loosely allied with the older synod, but in that year a national synod of the German Reformed Church in the United States was formed. Six years later the word German was dropped from the name. From time to time efforts were made to unite this church with the (Dutch) Reformed Church in America and with the Presbyterian Church in the U.S.A.; these attempts all failed. Union with the Evangelical (Lutheran) Synod was, however, successful in 1934.

The Evangelical Synod of North America dated from 1840 and was known in its early years as the Evangelical Union of the West. It was formed under the leadership of missionaries from Lutheran and Reformed churches of Germany and Switzerland who were engaged in pioneer work in Missouri and Illinois. The original organization was strengthened by amalgamations with the German Evangelical Church Association of Ohio, which took place in 1858, the German United Evangelical Synod of the East in 1860, the Evangelical Synod of the North-West in 1872, and the United Evangelical Synod of the East, also in 1872.

At the time of merger in 1934 the Evangelical Synod of North America had 281,598 members, the Reformed Church in the United States 348,189. The union was fully achieved only in 1940–41, as the Evangelical and Reformed Church.

The union of the Evangelical and Reformed Church with the Congregational Christian Churches was the first church merger in the United States which joined denominations of extremely varied theological and ethnic backgrounds. At the time of approval of its constitution in 1961 the Evangelical and Reformed synods reported about 814,000 members in 2,726 churches; the 3,665 Congregational Christian local churches had a membership of 1,108,000.

ASPECTS OF THE REFORMED CHURCHES

For the church polity of these bodies, *see* PRESBYTERIANISM: *The Presbyterian System.*

Worship.—Though like the Presbyterians in most ways, the Reformed churches differ in that they use established liturgies. Both groups agree in their concepts of worship. The Presbyterians believe these ideals are best achieved by allowing great freedom to each congregation, whereas the Reformed churches regard an established liturgy as a valuable aid in guiding a congregation into a right service of God. All these churches regard worship as only a part of the Christian congregation's total service of God. Cultic and ritual acts, as such, have no influence upon God. They are significant only in their bearing upon the congregation as the acts become the means whereby God becomes known to the congregation as Lord, Redeemer, and Judge. In all Reformed-Presbyterian worship, therefore, there is an emphasis on the Word of God made known and interpreted through preaching and the sacraments. The appeal is to the whole of the life of the congregation, as persons and as members of a society of persons. There is no access to God which does not involve one's neighbour. The sensuous, the symbolic, the nonverbal, are little emphasized in the interests of clarity, conscience, duty, and obedience. The function of worship is not the cultivation of the worshiper's religious feelings but the bringing of the sons of God more fully into the totality of the Divine purpose among all men. (*See* further PRESBYTERIANISM.)

Doctrine.—During the 16th century the various Reformed churches regarded creeds or confessions as teaching and disciplinary media. They considered it both desirable and necessary that each church body should have an adequate and contemporary creed or confession. Almost every Reformed church therefore drew up its own statement of faith. The best known of these confessions are the Second Helvetic Confession (1566) by Heinrich Bullinger, widely used in German-speaking Switzerland (*see* HELVETIC CONFESSIONS); the Genevan Catechism (1542) by Calvin (*see* CATECHISM); the Heidelberg Catechism (*q.v.*; 1563); the Belgic Confession (1561) of the Dutch church; and the Gallican Confession (1559), a revision and expansion by the Huguenots of an earlier draft by Calvin. (*See* further CONFESSIONS OF FAITH, PROTESTANT: *Reformed Churches;* PRESBYTERIANISM: *Presbyterian Thought.*)

Relations with Other Churches.—There has always been a certain ambivalence about those distinctive aspects of the Reformed churches which set them off from other Evangelical, or Protestant, bodies. The Reformed churches themselves regard nearly all of their distinctive aspects as being little more than the logical consequences of the basic Evangelical faith of any Protestant body. It has always been their policy, therefore, to define their relationship to other Evangelical churches on the basis of the Christian faith which they have in common, while insisting upon a stricter standard for their own members. Transfer of members, or of pastors, from other denominations has always been possible without any requirement of rebaptism, reordination, or other act which would call into question the former affiliation. Likewise, intercommunion (*i.e.*, freedom to receive the Lord's Supper) has always been open to members of all Evangelical bodies. Cooperative work in interdenominational enterprises has been facilitated also by this same attitude. Actual union of other bodies with Reformed bodies, however, has always raised the question of the more rigorous theological orientation in creed, polity, preaching, and social concerns.

REFORMED EPISCOPAL CHURCH, a Protestant community in the United States formed as a result of a division in the Protestant Episcopal Church. The influence of the Tractarian movement (*see* OXFORD MOVEMENT) began to be felt at an early date, and the ordination in New York, July 1843, of Arthur Carey, a clergyman who denied that there was any difference in points of faith between the Anglican and the Roman churches, brought into relief the antagonism between the evangelical Protestant clergy and those who sympathized with the position of Carey. The struggle went on for a generation and with increasing bitterness. The climax was reached when George David Cummins (*q.v.*), assistant bishop of Kentucky and a leader of the evangelicals, was angrily attacked for officiating at the united communion service held at the meeting of the sixth General Conference of the Evangelical Alliance in New York, October 1873.

Cummins resigned his charge in the Episcopal Church on Nov. 11, and a month later, with seven other clergymen (*see* also CHENEY, CHARLES EDWARD) and a score of laymen, constituted

the Reformed Episcopal Church. The church recognizes no "orders" of ministry; the episcopate is an office, not an order, the bishop being the chief presbyter, *primus inter pares.* It is governed by a General Council, which meets triennially. The church supports mission activities in India and Africa. Members number around 7,500. *See* also PROTESTANT EPISCOPAL CHURCH: *History: High and Low Church Divisions.*

REFORM MOVEMENT (BRITISH), a name given to the movement toward parliamentary reform in Britain which "culminated" in the passing of the "great Reform Bill" of 1832. It is difficult to date precisely its beginning, but most historians start with the rise of London radicalism in the years preceding the Middlesex election of 1768 when the House of Commons refused to allow John Wilkes, a popular hero, to take his seat. The end of the movement also is a matter of definition. Working-class radicalism, a relatively new phenomenon, associated with the rise of industry, was not satisfied with the settlement of 1832. The fight for the working-class vote antedated not only the drafting of the People's Charter in 1838 but the passing of the 1832 act, and Chartism emerged from older movements of protest. The agitation for the second Reform Bill of 1867 may also be said to be a continuation of the reform movement.

The Unreformed System.—The system of parliamentary representation which reformers attacked in the late 18th and early 19th centuries was the product of history. The 18th-century House of Commons consisted of 558 members, elected by 314 constituencies. The 245 English constituencies (40 counties, 203 boroughs, 2 universities) returned 489 members; the 24 Welsh constituencies (12 counties, 12 boroughs) and 45 Scottish constituencies (30 counties, 15 burghs) each returned one member. Ireland, with 100 members, was not represented at Westminster until the Act of Union of 1800 which abolished the separate Irish legislature.

The English franchises for the counties and boroughs differed fundamentally. The county franchise was based on the possession of freehold property, variously defined, but valued for the land tax, at 40*s.* per annum. In theory the county electors were able to choose their representatives freely, but in practice they were subjected to various forms of "influence." The borough franchise, by contrast, was based on no single criterion. There were six kinds of borough—household or "potwalloper" boroughs where the right of voting was held by all inhabitant householders not receiving alms or poor relief; freeman boroughs, where the right of voting was restricted to freemen, in some cases only to resident freemen; scot and lot boroughs, in which the right of voting was enjoyed by all inhabitant householders paying the poor rate; corporation boroughs, in which the right of voting was confined to members of the corporation; burgage boroughs, where the franchise was attached not to persons but to property, and could not be increased or diminished; and freeholder boroughs, where the right of voting lay with the freeholders, so that if one person owned a sufficient number of freeholds he could control the borough as easily as if the franchise were based on burgage tenure. There were only 6 freeholder boroughs and 29 burgage boroughs, but in the other types of borough there were varying sizes of electorate and varying degrees of venality. Even some of the potwalloper boroughs were controlled by patronage. "Pocket boroughs" were those where one person could usually control an election or dispense with it: "rotten boroughs" were boroughs whose existence it was difficult to justify except in terms of prescriptive right.

In the eyes of many reformers the defects of the system as a whole were more serious than particular abuses and anomalies. In the boroughs, in particular, there was a clear and increasing contrast between the distribution of electoral power and the facts of economics and geography. Large industrial cities, like Manchester and Birmingham, were unrepresented, and some of their most active and enterprising citizens lacked the vote. In Yorkshire the city of York and 13 other small boroughs with a total of 7,000 voters returned 28 members, while the county, with a population of 16,000 voters, returned only 2 members. Cornwall returned 44 members, against Lancashire's 14. The City of London, with a population of about 100,000, returned only 4 members.

Facts of this kind were put forward on a large scale for the first time on the eve of the 1768 election. An important "extraordinary number" of the *Political Register* in January 1768 complained about the limitations on the franchise, the nonrepresentation of "the monied interest" and of manufacturing towns, and the existence of rotten boroughs. "With regard to the representation," it asked, "what could blind chance have determined more unequal, irregular, and imperfect, than we see it today?" While the Wilkes case (*see* WILKES, JOHN) stirred the passions of London reformers, the Society of Supporters of the Bill of Rights was set up in 1769. This was the first of a number of societies which were to quicken the pace of politics in the late 18th and early 19th centuries by disseminating both facts and ideas and by organizing meetings and demonstrations.

War and Reform, 1775–1784.—The implications of the Wilkes case were freely discussed outside London, but it was the experience of the American Revolution which made the reform issue a major one in English politics. Two versions of "reform" became current during this period of strain and upheaval—"economical reform," centred on a reduction of the influence the government was able to exert through patronage, and "radical reform," involving a reconstruction of the electoral system. The parliamentary opposition to Lord North (prime minister from 1770 to 1782) made much of the first, and in 1779 and 1780, when the war news was alarming, there was a strong movement in the country pressing for far-reaching "economical reform." The Yorkshire Association, founded in 1779, set out, under the direction of Christopher Wyvill, to "restore the Freedom of Parliament." Middlesex also was stirred again, and radical feelings there often took more abstract form, particularly in the speeches and writings of John Jebb and Major John Cartwright, which provided the beginnings of a democratic theory of representation. Neither the Rockingham Whigs in Parliament nor the earl of Shelburne and his supporters were prepared to go as far as the most militant reformers outside Parliament. Edmund Burke, indeed, as a spokesman of the Rockingham Whigs, was opposed to organic parliamentary reform, and Shelburne, who was not opposed to it and believed in a more thorough "economical reform" than any other parliamentary politician, had more easy relations with provincial politicians like Wyvill than with the active Westminster Committee of Association and the Society for Constitutional Information which were founded in 1780.

Toward the end of the American war substantial measures of "economical reform" were carried, and motions for electoral reform won widespread parliamentary support. The Rockingham Whigs succeeded North in 1782 and passed a Civil Establishment Act in the same year. Shelburne in his short ministry of 1782–83 accomplished more substantial economic and administrative reforms. Thereafter, though there was still talk of "economical reform," parliamentary reform became the major political issue.

Pitt, The Reform Movement, and the French Revolution.—One of the youngest and most enthusiastic supporters of parliamentary reform at this time was William Pitt the Younger. In 1782, indeed, he moved for "a committee to enquire into the present state of the representation" and was defeated by only 20 votes, the best division the reformers achieved between 1780 and 1831. Even after becoming prime minister in 1783, Pitt continued to believe in reform. In 1785 he proposed *inter alia* that 36 rotten boroughs should be disfranchised and the vacant seats reallocated. Most of his own supporters were less enthusiastic than he was, and some were opposed. So too, for different reasons, were George III, North, and Charles James Fox. Leave to bring in his measure was refused, and Pitt abandoned his proposals. This was a final decision, for the French Revolution of 1789 not only effected a change in Pitt's ideas but made many erstwhile reformers join with conservatives in identifying reform with revolution.

In the first instance, however, the news of the French Revolution gave a fillip to reformers in Britain. The London Revolution Society, which had met in 1788 to celebrate the "glorious Revolution" of 1688, sent a congratulatory address to the French in 1789, and in April 1792 a group of advanced young Whigs, including Charles Grey, formed the Society of the Friends of the People. A

less exclusive body, the Society for Constitutional Information, which had been suspended since 1784, sprang into life again in 1791, inspired by the London reformer Horne Tooke, and looked to the French example. More significant, however, was the growth of reform sentiment, much of it of an extreme kind, in the provinces, in places as far apart as Stockport and Norwich, Coventry and Sheffield, and above all in Scotland. Particularly after 1792, with the writings of Tom Paine as an inspiration, "Jacobin" ideas were disseminated widely and effectively. The Sheffield Society for Constitutional Information declared, for example, that it had derived "more knowledge" from the works of Paine "than from any other author or subject." The most interesting of the societies was the London Corresponding Society, formally founded by Thomas Hardy, a shoemaker, in 1792. It consisted largely of working people, had many divisions or branches, had a low entrance fee and subscription, and advocated social as well as political objectives. In an *Address to the People,* published in August 1792, they promised "taxes diminished, the necessaries of life more within the reach of the poor, youth better educated, prisons less crowded, and old age better provided for."

Although the reform movement of these years was repressed, often cruelly, after 1794, the link between political action and economic grievance was to become more important in the reform movements of the future. Years of bad harvests and unemployment had always encouraged popular disturbance. Within an industrial system they were to provide a dynamic. The Luddite movement from 1811 onward was the prelude to specifically working-class movements for parliamentary reform after 1815. There were many other important developments before 1815. Westminster's radicalism revived in 1807, when Sir Francis Burdett was elected its member. William Cobbett was converted from Toryism to radicalism and began (1802) to publish his influential weekly *Political Register.* Jeremy Bentham (*q.v.*) had developed a new theoretical defense of democracy. New organizations also had been founded, notably the Hampden Club in 1812.

Toward 1832.—The years following the end (1815) of the Napoleonic Wars were bleak and discontented, with working-class agitation culminating in 1819 in "Peterloo." Among the key figures of this period were Henry ("Orator") Hunt, the proprietors of widely read radical newspapers like *The Black Dwarf,* and a new and more searchingly critical voice, Richard Carlile of *The Republican.* Working-class protest was less effective politically, however, than the growing middle-class agitation for parliamentary reform in the late 1820s, when, particularly in Birmingham, men like Thomas Attwood associated parliamentary representation with the demand for economic reform. The Birmingham Political Union, founded in 1829, was the most important extraparliamentary body in the struggles of 1831 and 1832. The struggles centred on a Whig Reform Bill introduced by Grey in 1831 soon after the Whigs had been returned to office after years in the political wilderness. Although the bill was opposed by Tories on the grounds that it marked the beginnings of a revolution and by militant reformers on the grounds that it was far too moderate, it was passed, after two serious political crises, in June 1832.

The new act redistributed seats and changed the conditions of the franchise: 56 English boroughs lost their representation entirely; Cornwall's representation was reduced to 13; 65 seats were transferred to the counties, and 42 new English boroughs were created. The electoral qualification in the counties was extended to cover £10 copyholders, leaseholders, and tenants at will paying a rent of not less than £50, while in the boroughs a uniform £10 household qualification became the basis of the vote. The Whigs hoped that the settlement of 1832 would be "final." Within five years, however, it was clear that the country would not treat it as such. The act marked the beginning of parliamentary reform, not the end. *See* also BOROUGH; CHARTISM; ENGLISH HISTORY; LUDDITES; PARLIAMENT.

REFRACTION. When waves of any kind traveling in one medium enter another, in which their velocity is different, their direction is, in general, changed, the rays, *i.e.,* the lines perpendicular to the wave surfaces (in isotropic media) along which the energy travels, being bent or refracted at their point of incidence on the second medium. The change in direction is such that the sine of the angle formed by the incident ray and the normal to the surface of separation bears the same ratio to the sine of the angle formed by the refracted ray and this normal, as the velocity of the waves in the first medium to their velocity in the second. This ratio, known as the refractive index, may depend on the frequency of the wave vibrations. If such be the case, each frequency in the incident disturbance gives rise to a separate refracted ray—a phenomenon known as dispersion. (*See* OPTICS.)

Mirage (*q.v.*) is due to the refraction of light by layers of air of gradually varying temperature and density. A similar variation, due to convection currents, is responsible for the flickering appearance seen above asphalt and sand on a hot day, and also for the twinkling of the stars. The refraction of rays of light entering the earth's atmosphere from heavenly bodies is known as astronomical refraction; it has the effect of making such bodies appear higher above the horizon than they really are. *See* LIGHT; REFRACTOMETER; SOUND: *Reflection and Refraction of Sound. See* also references under "Refraction" in the Index.

REFRACTOMETER, an optical instrument for measuring refractive index. The refractive index n of a substance is equal to the speed of light V_m in that substance divided into the speed of light V_s in a standard medium: $n = V_s/V_m$. The standard medium is usually air or, in the case of gases, a standard partial vacuum. Each pure substance has a unique value of n under standard conditions of temperature, pressure, and wave length.

Refractometers are generally either of the deviation type or interference type, depending on the utilized change in light waves passing from one medium into another. These changes result from the different speeds of light in the two media and consist of: (1) a change in direction when the light strikes the boundary surface obliquely; and (2) a change in the phase of vibration of the light wave. A third, less common, type of refractometer makes use of the ratio between the intensities of light reflected and incident on an interface between two media. Sensitive photoelectric cells allow the rapid detection of small changes in refractive index by the photometric method.

A number of variables must be accurately controlled in precision refractometry. These are mainly temperature, wave length of light, and optical alignment of parts. An increase in temperature of 1° C gives, for most liquids, a decrease in n by several units in the fourth decimal. The refractive index of a colourless substance measured with red light may be as much as several units in the second decimal smaller than when measured with violet light. The most widely used monochromatic light source is the sodium lamp; unless otherwise stated, values of n refer to the average wave length of the yellow sodium spectral lines (5,893 Å). Electric-discharge tubes containing such elements as helium, hydrogen, cadmium, or mercury provide a series of well-defined wave lengths that are often used to determine optical dispersion.

Instruments designed to give fourth- or fifth-decimal accuracy require the highest quality workmanship in their optical and mechanical construction and adjustment. Reliable refractometric measurements require frequent calibrations of the instrument with known standards. The greatest accuracy is obtained by a direct comparison of the unknown with a similar known substance. The critical-angle and interference-type refractometers allow this kind of technique, known as the differential method. Easily purified liquids, such as water, serve as convenient standards of comparison; glass test plates are also used. The U.S. National Bureau of Standards has made available a series of pure hydrocarbons with refractive indices certified to the fifth decimal.

Deviation-Type Instruments.—*Optical Principles.*—Basic to all such instruments is Snell's law of refraction: $n = \sin i/\sin r$. The angle of incidence i and the angle of refraction r are the angles

made with the normal (*i.e.*, perpendicular) to the boundary surface by the rays in the first and second media, respectively. The

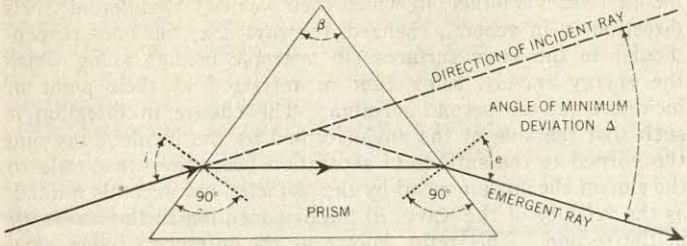

FIG. 1.—PRINCIPLE OF MINIMUM DEVIATION, USED WITH SPECTROMETER TO DETERMINE REFRACTIVE INDEX n OF PRISM: $n = \text{SIN } \frac{1}{2}(\beta + \Delta)/\text{SIN } \frac{1}{2}\beta$

angles i and r are usually found indirectly from the deviations of rays that traverse not only the sample but one or more prisms and lenses of the refractometer as well. In the spectrometer type of instrument the incident rays come from a narrow slit so that, with a proper lens system, the refracted rays can be located precisely with the aid of a telescope. The spectrometer is ordinarily used with the principle of minimum deviation, which states that the angle between incident and emergent rays (fig. 1) can be made a minimum Δ by a unique orientation of the prism. Under these conditions $i = e$, and the refractive index of the prism is $n = \sin \frac{1}{2}(\beta + \Delta)/\sin \frac{1}{2}\beta$, where β is the angle between the refracting faces of the prism (*see* SPECTROSCOPY).

Critical-angle refractometers make use of particular incident and refracted rays. The critical angle of refraction C is the greatest value of r that can be attained by any ray passing from a less to a more refracting medium (fig. 2). According to Snell's law, C corresponds to an incident ray that grazes the intersurface between the two media ($i = 90°$). All other refracted rays come closer than C to the normal direction. In critical-angle refractometers a prism of known refractive index n_p is used as the more refracting medium. A beam of nonparallel rays passes through the sample into the prism. On viewing the light refracted through the prism by means of a telescope, one finds a sharp critical boundary between a dark and a light region (fig. 2) that very precisely defines the rays having the angles $i = 90°$ and $r = C$. The refractive index of the sample is given by the equation $n = n_p \sin C$.

Abbe Refractometer.—This instrument is perhaps the most widely used critical-angle instrument. The ordinary model is

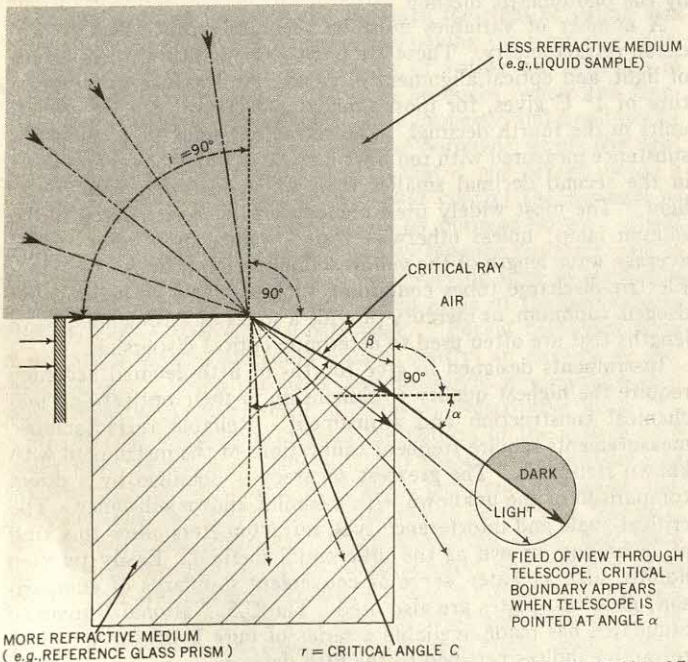

FIG. 2.—CRITICAL ANGLE OF REFRACTION. RAYS HAVING AN ANGLE OF INCIDENCE OF EXACTLY 90° APPEAR IN THE VIEWING TELESCOPE AT THE SHARP BOUNDARY BETWEEN A LIGHT AND A DARK REGION, HENCE THEIR ANGLE OF REFRACTION CAN BE MEASURED ACCURATELY

rugged, compact (about the size of a microscope) and is capable of fourth-decimal accuracy. Only a few drops of a liquid sample are required, and a determination may be completed in less than five minutes. Liquid samples are confined to a thin film between the surfaces of the refracting prism P (fig. 3), $\beta = 60°$, and an adjacent auxiliary prism P'. The latter prism serves to send light into the sample in the direction required for the critical boundary. If white light is used, the critical boundary is not sharp because of the different refraction of rays of different wave length.

Most Abbe models are provided with a pair of compensating prisms, mounted in the barrel of the telescope, which remove nearly all of the boundary colour and sharpen the boundary. The amount of rotation of one compensating prism relative to the other, required to achromatize the boundary, provides a rough measure of the dispersion of the sample. The compensating system is designed to give refractive indices corresponding to a wave length near that of the sodium lines. The prisms holding the sample can be rotated with respect to the telescope about an axis passing through the point R (fig. 3). With a solid or liquid sample

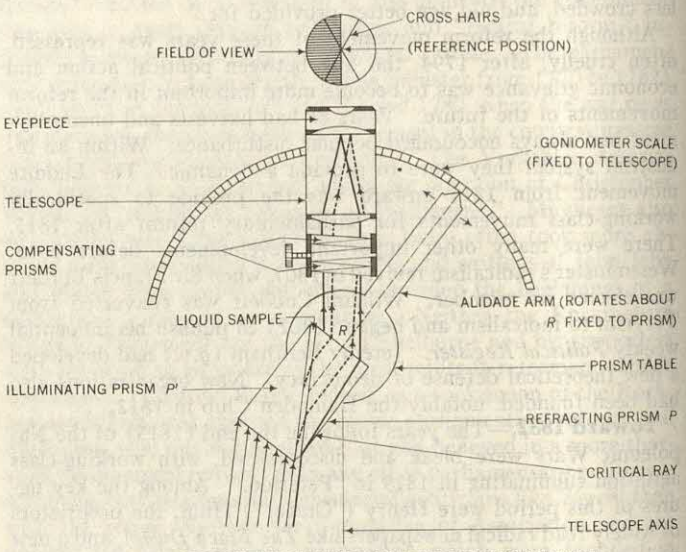

FIG. 3.—SCHEMATIC DIAGRAM OF ABBE REFRACTOMETER

on the lower face of the prism P, the critical boundary can be made to coincide with the cross hairs in the telescope by rotating the prism by means of the alidade arm and a slow-motion screw. A pointer attached to the arm indicates the degree of rotation on a circular scale attached to the telescope. The scale may read directly in terms of refractive index n or, as desired, in terms of concentration of some solute. The range of each instrument is limited by the refractive index of the prism. Usually refractive indices from 1.3 to 1.7 can be covered.

Dipping or Immersion Refractometer.—This instrument resembles the Abbe instrument without the auxiliary prism P'. The refracting P is directly immersed in liquid samples, and the critical boundary is located with respect to a movable eyepiece scale. The dipping refractometer is widely used to check the concentration of solutions. The use of interchangeable prisms gives it a greater range than the Abbe type.

Other Types.—Deviation-type instruments, such as spectrometers, cover an unlimited range of refractive indices and, when appropriately designed, can be used with ultraviolet or infrared light. The material under investigation must be in the form of an accurately shaped prism. Liquid samples are placed in a prismatic cell. Monochromatic or polychromatic light from a narrow slit is made parallel by a collimating lens before traversing the prism. For each wave length an image of the slit is located by means of a telescope mounted on a graduated circle. The many necessary careful adjustments make the spectrometer inconvenient for routine use. Its principle is employed, however, in a number of simplified image-displacement refractometers. Some of these are designed for rapid measurement of small liquid samples. The sample is made into a tiny prism by placing a drop between a

pair of glass surfaces. If an illuminated slit is viewed through such a prism, its apparent position is shifted from its true position by an amount that depends on the refractive index of the sample and the angle of the prism. The amount of image displacement can be observed on a scale mounted behind the prism. A variation of this principle is found in the Nichols refractometer, which uses a microscope to observe the image displacement. The ordinary microscope can be adapted for use as a simple refractometer of this type.

Interference-Type Instruments.—Interference refractometers are indispensable for finding the refractive indices of gases; they can also be used for liquids and some solids. The interferometric method offers the most convenient means for determining the concentration of a substance in an extremely dilute solution.

FIG. 4.—SCHEMATIC DIAGRAM OF RAYLEIGH-HABER-LÖWE INTERFERENCE REFRACTOMETER

Differences in refractive index of one part in a million may be detected easily, and still higher sensitivities have been attained. Such small differences may be of practical importance, as in the industrial analysis of air. Portable interference refractometers have been used to detect traces (0.1%) of methane (marsh gas) in coal-mine air as a means of preventing explosions.

Optical Principles.—In the interference-type refractometer a set of interference bands is produced by the superposition of two light beams originating at the same slit source. When a transparent substance having a refractive index n is placed in the path of one of the beams while the other beam travels a comparable distance in a material of index n_0, there is a displacement of the interference bands that depends on the difference $n - n_0$.

The relation between refractive index and band displacement can be understood by considering the superposition of two converging trains of wave fronts. If they originate at the same slit source, there is a series of locations along the wave fronts where the waves are in the same phase of vibration and reinforce each other to produce a maximum light intensity. At intervening places the waves will be out of phase and tend to annul each other. One then sees alternately bright and dark areas in the field of view. These interference bands usually appear as narrow vertical fringes. If one of the wave trains is slowed down somewhat by passing through a more refracting medium than the other, the locations of the maxima and minima will be displaced laterally.

A relative retardation by one wave length causes the bands to shift laterally by one fringe interval. The band displacement, in number of fringe intervals N, is consequently related to the refractive index n by the formula $n - n_0 = \lambda N/t$, where λ is the wave length of the light and t is the thickness of the interposed sample.

Rayleigh Refractometer.—The basic elements of the Rayleigh interference refractometer (fig. 4) are two achromatic lenses of long focal length, the first for obtaining parallel rays from a narrow slit source, the second for bringing together two beams, B_I and B_{II}, emerging from two broad slits in front of the first lens. The resulting interference bands are observed with the aid of a cylindrical lens focused on the focal plane of the second achromatic lens. Adjacent cells C_1 and C_2, each in the path of one of the beams B_I and B_{II}, contain the reference substance and the sample.

Commercial instruments are usually of the Rayleigh-Haber-Löwe type (fig. 4), which uses the Jamin method of determining the band displacement. B_I and B_{II} are so divided that there are actually four beams: B_I, B_{II}, b_I and b_{II}. The lower beams, b_I and b_{II}, pass through air and the lifting prism (Pr). The upper beams, B_I and B_{II}, pass through cells C_1 and C_2 and movable plate P_1 and fixed plate P_2, respectively. Instead of counting the bands the observer increases the path in the glass by tilting the plate P_1 to produce a retardation just equal to that produced by the sample in the other beam. The effective thickness of P_1 is adjusted by the tilting lever L and a graduated micrometer screw. The micrometer scale may be calibrated to read values of $n - n_0$. The screw M is turned until the central interference band is brought back into the position it had before the sample was introduced. The central band in white light can be recognized because it is the only one having a pure white colour. *See* also INTERFEROMETER; LIGHT; OPTICS.

Automatic Recording Refractometers.—Instruments of this nature show promise of wide application in science and industry as a means of detecting small changes in flowing gases and liquids. Any of the types of refractometers may be adapted to automatic recording by substituting a photoelectric cell for the human eye. The current through the cell provides a measure of the intensity of light falling on the cell at a definite location.

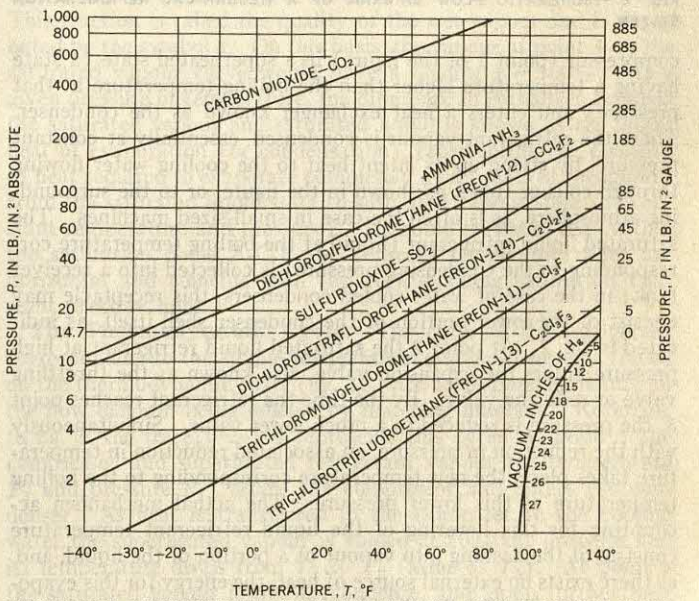
REFRIGERATION, the process of lowering the temperature inside an insulated enclosure by extracting heat and rejecting it to the surroundings or some other external medium of higher temperature. Since heat will not flow spontaneously from a region of low temperature to one of higher temperature, mechanical work or heat energy from an external source must be expended to move the heat from the enclosure to be refrigerated.

Refrigeration technology draws its basic knowledge from three interrelated yet distinct areas of science, namely, thermodynamics, heat transfer, and fluid flow. As refrigeration technology has advanced, improved processes and materials have made possible many consumer products and industrial applications, from kitchen refrigerators and ice-cube makers to spot-cooling of electronic devices and simulating Arctic conditions for testing and research.



REPRINTED FROM THE DESIGN VOLUME OF THE 1942 "ASRE DATA BOOK" BY COURTESY OF THE AMERICAN SOCIETY OF REFRIGERATING ENGINEERS

FIG. 1.—PRESSURE AND TEMPERATURE RELATIONSHIP OF VARIOUS LIQUID REFRIGERANTS

In the following sections the underlying principles of operation of major refrigeration systems (mechanical compression, absorption, and thermoelectric) are discussed, drawing on the basic sciences only to the extent necessary to achieve understanding and clarity.

In all mechanical compression and absorption refrigeration systems the working fluid used to carry away the heat from the region to be cooled is known as the refrigerant. The boiling temperature of refrigerants, like that of any other liquid, depends on the pressure at which the boiling takes place, the boiling temperature decreasing with decreasing pressure. This boiling temperature *v.* pressure characteristic of refrigerants can be said to constitute the main principle of operation (fig. 1). It is to be noted that, at a given pressure, the phenomena of boiling and condensation take place at the same temperature, one process being the reverse of the other.

MECHANICAL COMPRESSION REFRIGERATION SYSTEMS

The most widely used refrigeration cycle is the mechanical compression refrigeration cycle, which is schematically illustrated in fig. 2. A high-pressure refrigerant vapour is discharged from the compressor (point 1 of the figure) in a superheated state (a state having a temperature higher than the boiling temperature at that pressure) and enters a heat exchanger known as the condenser. There the refrigerant vapour is condensed, essentially at constant pressure, by giving up its latent heat to the cooling water flowing through coils or tubes, as shown in the figure, or to the surrounding atmosphere, as is often the case in small-sized machines. The saturated liquid refrigerant (liquid at the boiling temperature corresponding to the condensing pressure) is collected into a receiver tank; in the case of water-cooled condensers, this receptacle may consist of the lower portion of the condenser shell itself, as indicated in fig. 2. At point 2 the saturated liquid refrigerant at high pressure enters the expansion valve, also known as the throttling valve or reducing valve. By the time the refrigerant reaches point 3, the pressure is reduced to a much lower value. Simultaneously with the reduction in pressure, an associated reduction in temperature takes place, the new temperature corresponding to the boiling temperature at this lower pressure. The actual mechanism accounting for this lowering of the liquid refrigerant temperature consists of the flashing into vapour of a portion of the liquid, and, as there exists no external source of heat, the energy for this evaporation is supplied by the liquid refrigerant itself, thus causing its temperature to drop. At point 3 the low-temperature liquid refrigerant, with a small fraction of its vapour, is admitted to a heat exchanger known as the evaporator. Within the evaporator (which may be constructed in a variety of designs) the liquid refrigerant is evaporated by heat transferred to it from the comparatively warmer space to be refrigerated. The flow rate of the refrigerant is so adjusted by the thermostatic expansion valve that at the exit of the evaporator, at point 4 in the system, all the liquid refrigerant is in the saturated vapour state (vapour at the boiling temperature corresponding to the evaporator pressure). The vapour leaving the evaporator enters the suction side of the compressor and is compressed to a higher pressure. The work of compression raises both the pressure and temperature of the refrigerant vapour so that it is discharged in the superheated vapour state and ready to repeat the entire cycle over again.

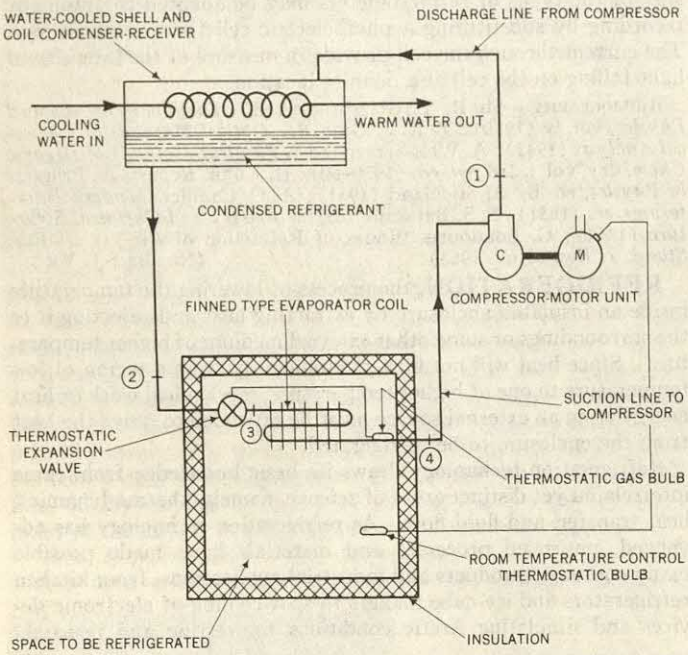


FIG. 2.—SCHEMATIC FLOW DIAGRAM OF A MECHANICAL REFRIGERATION SYSTEM

A cycle of the type described above is known as a steady-flow thermodynamic cycle because at any one point in the cycle refrigerant conditions (*i.e.*, flow rate, temperature, pressure, etc.) do not change with time, while heat and work are received by the refrigerant in the evaporator and compressor, respectively, and heat is rejected in the condenser. Also, this cycle operates between two levels of pressure and two corresponding levels of temperature. The high-pressure half of the cycle extends from the discharge of the compressor to the inlet of the expansion valve, and the low-pressure side extends from the discharge of the expansion valve to the inlet of the compressor.

Thermodynamic Analysis of Compression Refrigeration Cycles.—Evaluation of the performance of the various components of the refrigeration cycle discussed above requires a knowledge of some of the laws of thermodynamics that govern the interconversion of heat and work and enable the calculation of the thermal properties of substances. Extensive tables of thermodynamic properties of all commonly used refrigerants have been prepared and are available in tabular or graphical form readily usable in engineering calculations (*see* HEAT; THERMODYNAMICS).

From the principle of conservation of energy it can be stated that for a fluid in steady flow the summation of all its energy quantities (its total energy) entering a system (compressor, heat exchanger, etc.) must be equal to the summation of all its energy quantities leaving the system. For a unit mass flowing in and out of a system per unit time this principle can be written in symbolic form as:

$$u_1 + A(P_1v_1) + A(V_1^2/2g) + AZ_1 + {}_1Q_2 = u_2 + A(P_2v_2) + A(V_2^2/2g) + AZ_2 + A({}_1Wk_2) \qquad (1)$$

In the above relation subscripts 1 and 2 refer, respectively, to the magnitudes of the various quantities as the fluid enters and leaves the system. The magnitude of the various quantities can be expressed in any consistent set of units such as the British system of engineering units employed here, and where u = internal energy of the fluid, its value depending on the temperature and pressure of the fluid, expressed in British thermal units (BTU) per pound (one BTU is the quantity of heat required to raise the temperature of one pound of water by one degree Fahrenheit [from 63° F to 64° F]); P = pressure of the fluid, in pounds per square foot; v = specific volume of fluid, in cubic feet per pound; V = velocity of the fluid, in feet per second; Z = elevation of the inlet to the system measured from an arbitrary reference level, in feet; ${}_1Q_2$ = heat transferred to or away from the fluid from the time it enters to the time it leaves the system, in BTU per pound of fluid flowing (by convention, ${}_1Q_2$ is taken as positive if the fluid receives heat and negative if it gives up heat); ${}_1Wk_2$ = external work done by the fluid or on the fluid from the time it enters to the time it leaves the system, in foot-pounds per pound of fluid flowing (by convention, ${}_1Wk_2$ is taken as positive if it is performed by the fluid and negative if it is performed on the fluid); g = gravitational acceleration whose standard value is 32.2 ft. per square second; A = the mechanical equivalent of heat, a universal constant used to convert units of work into units of heat and vice versa ($A = \frac{1}{778}$ ft-lb. per BTU).

Examining equation (1) further, Pv, the product of the pressure times the volume, represents the magnitude of the flow work necessary to set the fluid in motion; $V^2/2g$ represents the kinetic energy caused by motion; and Z represents the potential energy of the

moving fluid measured above a given arbitrary reference datum plane. In thermodynamics, because of the frequent simultaneous occurrence of the terms u and Pv, a new term called enthalpy is defined as $h = u + Pv$ (the sum of the internal energy of the fluid or body and the product of its volume multiplied by the pressure). Hence, the quantity $(u_1 + AP_1v_1)$ can be written as h_1 and $(u_2 + AP_2v_2)$ as h_2. Making these substitutions and transposing some of the terms, equation (1) can be rewritten in the form

$$h_2 - h_1 = {}_1Q_2 - A({}_1Wk_2) + A(V_1^2 - V_2^2)/2g + A(Z_1 - Z_2) \qquad (2)$$

Equations (1) and (2), which are identical, are known as the general energy equations for steady flow and are used extensively in engineering calculations involving the interchange of heat and work. To simplify the analysis of refrigeration cycles it is common practice to neglect the last two terms on the right-hand side of equation (2), since their magnitude is either zero or negligible compared with the others. In fact, the difference in elevation between the inlet and outlet openings or the difference in velocity between the inlet and outlet of compressors or heat exchangers is either nil or negligible. Equation (2) can then be reduced to the form

$$(h_2 - h_1) = {}_1Q_2 - A({}_1Wk_2) \qquad (3)$$

Equation (3) may be applied to any of the components that make up the refrigeration system shown in fig. 2. Considering the condenser, the refrigerant receives no external or shaft work and delivers none as it enters and leaves this equipment, and only heat is exchanged between the condensing refrigerant and the cooling water. Therefore in equation (3) the quantity ${}_1Wk_2$ is zero, and the decrease in enthalpy of the refrigerant $(h_2 - h_1)$ is equal to the heat it rejects to the cooling water, ${}_1Q_2$. The evaporator is a similar piece of equipment and again there is no work involved; therefore, the heat absorbed from the space to be refrigerated is equal to the increase of enthalpy of the evaporating refrigerant, ${}_3Q_4 = (h_4 - h_3)$. The flow through the expansion valve involves neither the exchange of heat nor work, hence, in this instance, equation (3) yields the result $h_3 - h_2 = 0$, indicating that the refrigerant undergoes no change of enthalpy. In the case of the compressor a definite amount of work, ${}_4Wk_1$, is delivered to the refrigerant vapour being compressed. While some heat, ${}_4Q_1$, is dissipated from the compressor cylinder head to the surrounding atmosphere by convection and radiation, this quantity is usually a small fraction of the total work input and may be neglected in most instances without causing serious error. Where more exact calculations are desired or, in the case of jacketed water-cooled compressors, where the heat loss from the compressor cylinder is appreciable, in applying equation (3) either the quantity ${}_4Q_1$ must be known or a different expression should be used to evaluate the work required for compression. Such an expression has the general form

$$Wk_{comp.} = [n/(n-1)]P_4v_4[1 - (P_1/P_4)^{(n-1)/n}] \qquad (4)$$

where all symbols are as defined before and n is a constant which depends on the nature of the refrigerant, the type of compression (the extent of heat loss during compression), and the pressure range over which the compression takes place. Values of n are determined experimentally and are reported in reference works on refrigeration. An important observation to be made in equation (4) is the fact that the work of compression depends primarily on the pressure ratio of compression and not on the absolute values of the inlet or discharge pressures.

The Thermodynamic Diagram.—In solving refrigeration problems it is helpful to trace the processes the refrigerant undergoes on a chart of thermodynamic properties of the refrigerant, such as the pressure v. enthalpy chart shown in skeletal form in fig. 3, where the interrelationship between three of the most frequently used properties of refrigerants (pressure, enthalpy, and temperature) is graphically depicted. The properties pressure and enthalpy are chosen as the coordinates for the figure, and their variation with temperature is represented by the family of constant temperature lines T_4, T_4', T_2', T_2, T_1, T_1', in order of increasing temperature. The dome A-C-B is known as the saturation dome. Points along the curve A-C represent states of dry saturated vapour and along B-C states of saturated liquid. The saturated vapour and saturated liquid curves meet at point C, which is known as the critical point. At this unique temperature and pressure the liquid and vapour phases of the refrigerant are indistinguishable and therefore possess identical properties known as the critical properties of the refrigerant. The region to the right of the saturated vapour curve A-C represents states of superheated vapour, and that to the left of the saturated liquid curve B-C represents states of subcooled (or compressed) liquid (liquid at a temperature lower than the condensation temperature corresponding to the same pressure). The region within the dome A-C-B (wet vapour region) represents states of mixtures of liquid and vapour refrigerant. The percentage by weight of vapour in the mixture at any point within the dome is obtained by taking the ratio of the horizontal distance between the saturated liquid curve and the point in question to the total distance between the two saturation curves (measured at the same pressure). For example, at point 3 (fig. 3) the percentage of vapour in the mixture is given

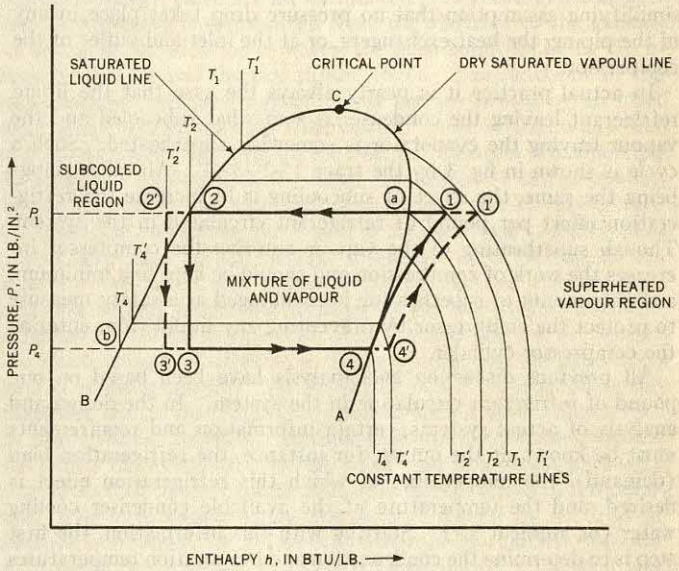

FIG. 3.—SKELETAL THERMODYNAMIC DIAGRAM ILLUSTRATING THE REFRIGERANT CYCLE FOR THE SYSTEM SHOWN IN FIG. 2 (NUMBERS CORRESPOND TO POINTS IN FIG. 2)

by the ratio of distances (b to 3)/(b to 4) or $(h_3 - h_b)/(h_4 - h_b)$. This fraction is called the quality of the wet vapour and is designated by the symbol x. On this basis, the vapour at point 4 on the saturated vapour curve would have a quality $x = 100\%$. At a given pressure or temperature, the difference in enthalpies between the saturated vapour and saturated liquid is known as the latent heat of evaporation (or condensation), representing the quantity of heat required to evaporate completely a unit mass of refrigerant from the saturated liquid state to saturated vapour state (at constant temperature and pressure). It should be noted that within the saturation dome A-C-B the constant temperature lines are horizontal and coincide with the corresponding saturation constant pressure lines.

The Thermodynamic Cycle.—The cycle of the refrigerant corresponding to the simple refrigeration system of fig. 2 is traced on the thermodynamic chart (fig. 3), with corresponding points on the flow diagram being labeled by matching numbers. Referring to fig. 3, the trace 1–2–3–4 represents this cycle. At point 1 the compressed and superheated refrigerant vapour (at temperature T_1 and pressure P_1) leaves the compressor and enters the condenser. As heat is transferred in the condenser to the cooling water the superheated vapour is cooled at constant pressure and its temperature drops from T_1 to T_2 (same as T_a). At point a the saturated vapour begins to condense, and, upon further heat transfer, condensation continues between points a and 2, the vapour giving up its latent heat of condensation until at point 2 all of the vapour is completely liquefied and is collected in the lower part

of the condenser (or a receiver) as saturated liquid. At point 2 the saturated liquid refrigerant enters the expansion valve, and its pressure is reduced from P_1 (same as P_2) to P_3 ($P_3 = P_4$). As shown earlier, the enthalpy of the refrigerant entering and leaving the expansion valve is the same; *i.e.*, $h_2 = h_3$. As a result of this pressure drop the temperature of the refrigerant is reduced to T_3 (same as T_4) at the expense of some of the liquid flashing into vapour. The fraction of the liquid flashed (the quality) is given by the ratio $x_3 = (h_3 - h_b)/(h_4 - h_3)$. At point 3 the refrigerant (mixture of liquid and vapour) enters the evaporator, and, as it absorbs heat from the refrigerated space and its contents, it continues to evaporate at constant pressure and temperature until at point 4 all of the refrigerant is completely evaporated and leaves the evaporator as saturated vapour. The dry saturated vapour enters the compressor at point 4, and by means of external work it is compressed along the path 4–1 and is discharged at point 1 to repeat the cycle. The cycle just described is known as the simple saturation ideal cycle because the refrigerant entering the expansion valve and the compressor consists of saturated liquid and saturated vapour, respectively. It is called ideal because of the simplifying assumption that no pressure drop takes place in any of the piping, the heat exchangers, or at the inlet and outlet of the compressor.

In actual practice it is nearly always the case that the liquid refrigerant leaving the condenser is somewhat subcooled and the vapour leaving the evaporator is somewhat superheated. Such a cycle is shown in fig. 3 by the trace 1′–2′–3′–4′. All other things being the same, the effect of subcooling is to increase the refrigeration effect per pound of refrigerant circulated in the system. Though superheating of the vapour entering the compressor increases the work of compression and should be kept to a minimum, a slight amount of superheating is encouraged as a safety measure to protect the compressor by preventing any liquid from entering the compressor cylinder.

All previous discussion and analysis have been based on one pound of refrigerant circulating in the system. In the design and analysis of actual systems, certain information and requirements must be known at the outset, for instance, the refrigeration load (demand), the temperature at which this refrigeration effect is desired, and the temperature of the available condenser cooling water (or ambient air). Starting with this information, the first step is to determine the condensation and evaporation temperatures and pressures for the refrigeration cycle. In practice, it is customary to assume an average temperature difference between the cooling medium and the condensing refrigerant of the order of 10° F. A similar figure is taken for the temperature difference between the evaporating refrigerant and the refrigerated medium. The smaller the temperature differential, the larger becomes the required size of the heat exchanger needed to accomplish a given heat transfer. Hence, the actual selection of temperature differentials to be used is based on both engineering and economic considerations. In general, therefore, one can write

$$T_c = (T_{c.w.})_{av.} + (\Delta T)_c \text{ and } T_e = T_r - (\Delta T)_e \qquad (5)$$

where T_c, T_e and T_r are the temperatures of the condensing and evaporating refrigerants and refrigerated medium, respectively; $(T_{c.w.})_{av.}$ is the average cooling water or air temperature; $(\Delta T)_c$ and $(\Delta T)_e$ are the design temperature differentials between the cooling water and condensing refrigerant and between the refrigerated medium and evaporating refrigerant, respectively, all temperatures being expressed in degrees Fahrenheit.

At this point the choice of a refrigerant must be made. The proper refrigerant selection is dependent primarily on the condenser and evaporator temperatures. A desirable refrigerant should not give rise to either unduly high condenser pressures or very low evaporator pressures. Some of the characteristics of refrigerants are discussed in a later section. Having decided on the refrigerant to be used and having determined the condensing and evaporating temperatures, the respective pressures are directly obtained by looking up the saturation pressures corresponding to these two temperatures. The next step in the analysis is the determination of the flow rate of refrigerant necessary to provide the desired refrigeration. Refrigeration load is commonly expressed in the unit of tons of refrigeration. In the U.S., one ton of refrigeration is equal to a cooling rate of 288,000 BTU per 24-hr. day, or 200 BTU per minute. The ton as the unit of refrigeration derives its name from the fact that to freeze one ton of water per day (one U.S. ton equals 2,000 lb.) from 32° F liquid to 32° F solid requires approximately 288,000 BTU. In Great Britain and Europe the ton of refrigeration is sometimes defined either on the basis of the long ton (2,240 lb.) or taken equal to a cooling rate of one kilocalorie per second. These units are larger than the U.S. ton by 12 and 18.8%, respectively. Referring to the cycle 1–2–3–4 of fig. 3, the refrigeration performed per pound of refrigerant is given by $(h_4 - h_3)$, in BTU per pound; hence, the required refrigerant flow rate, w, is

$$w = \text{(tons of refrigeration) } 200/(h_4 - h_3), \text{ pounds per minute}$$

The work necessary for compression is obtained from the relation

$$Wk_{comp.} = w(h_1 - h_4)/42.42, \text{ hp.}$$

where 42.42 is a conversion factor between heat units and horsepower (1 hp. = 42.42 BTU per minute).

A final quantity of interest in the analysis of refrigeration cycles is the efficiency of performance of the cycle. The efficiency of refrigeration cycles, which is known as the coefficient of performance (COP), is defined as the ratio of the refrigeration effect produced in the evaporator to the compressor work necessary to bring about this refrigeration effect. In symbolic form this may be expressed as

$$\text{COP} = w(h_4 - h_3)/w(h_1 - h_4) = (h_4 - h_3)/(h_1 - h_4)$$

The COP of all mechanical refrigeration cycles is greater than one. Since the magnitude of the COP is not directly indicative of the degree of perfection attained by an actual refrigeration system, it is often compared with the COP of an ideal cycle operating between the same condensing and evaporating temperatures. Such an ideal cycle is the Carnot cycle, named after its originator, Nicolas Sadi Carnot, the French engineer (*see* HEAT: *Carnot: On the Motive Power of Heat*). It can be shown in thermodynamics that a refrigeration system operating on the Carnot cycle requires the least amount of work per unit of refrigeration. It can further be shown that the COP of the Carnot cycle is independent of the type of refrigerant used and is fixed solely by the two temperatures at which heat is rejected and received. The COP of the Carnot cycle is defined as

$$(\text{COP})_{\text{Carnot}} = T_e/(T_c - T_e) \qquad (6)$$

where T_e and T_c are the evaporation and condensation temperatures, respectively, expressed in degrees Rankine. Temperatures in degrees Rankine are obtained by adding 460 to Fahrenheit degrees (*see* THERMOMETRY).

Properties of Refrigerants.—Since the early days of mechanical refrigeration the number of available refrigerants has increased steadily as a result of the consistent efforts of chemists and physical chemists searching for new fluids possessing suitable thermal, physical, and chemical characteristics to meet demands of new applications and equipment design. The most striking example of such research is the development of the series of refrigerants known under the trade name of Freons (*q.v.*). With rapid advances in the understanding of the structure of matter it has become possible to synthesize almost any type of refrigerant suitable for a specific application. However, even scientific progress has not been able to produce the ideal refrigerant having simultaneously optimum thermodynamic, physical, and chemical properties. Therefore, refrigerant suitability for a specific application is determined as a result of both engineering and economic considerations, and compromises must be made among the most important factors involved in a particular situation.

ABSORPTION REFRIGERATION SYSTEMS

Absorption refrigeration systems use heat energy directly through the medium of a generator-absorber-pump circuit, which replaces the complex mechanical compressor. In some absorption

refrigerators a small liquid pump constitutes the only moving part in the entire system, and in others even this is eliminated, resulting in a system with no moving parts whatsoever. Two of the most prominent types of absorption systems are discussed below.

The Ammonia-Water Absorption Refrigeration Cycle.—The most common absorption system is the two-fluid, water-ammonia (also known as aqua-ammonia) system. The operation of this system is based on the particular relationship between the temperature, pressure, and concentration of a mixture of two fluids, such as ammonia and water, while it undergoes a change of phase. When a mixture of ammonia and water boils at a given pressure, the vapour phase is much richer in ammonia (the more volatile of the two components) than the liquid phase in contact with it. Conversely, when condensing a mixture of ammonia and water vapour the condensate is poorer in ammonia than the vapour mixture in contact with it. Also, at a given pressure the boiling point temperature of the mixture decreases with increasing concentration of ammonia. This behaviour can be interpreted to mean that at low temperatures the mixture can hold more ammonia in solution than at high temperatures. Increasing the pressure on the mixture at constant temperature has the same effect. Finally, as is the case with single-component liquids, at a given concentration the boiling temperature of the mixture increases with increasing pressure. These basic behaviour characteristics of binary (two-component) mixtures will help in understanding the operation of the absorption system schematically shown in fig. 4 (*see* SOLUTIONS). Liquid ammonia (point 2) at about 85° F and 160 psi (pounds per square inch) is expanded through the expansion valve to about 22 psi and 15° F and enters the evaporator where it evaporates, absorbing heat from the space to be refrigerated. This ammonia vapour is discharged into the absorber (point 3), where it meets a shower (point 8) of weak liquor (about 30% ammonia), which absorbs the ammonia vapour into solution as it trickles down successive trays, thus forming a solution stronger in ammonia (about 38%). This strong liquor is pumped from the absorber to the top of the analyzer (point 5), being partly heated on its way as it passes through the heat exchanger. In the analyzer this

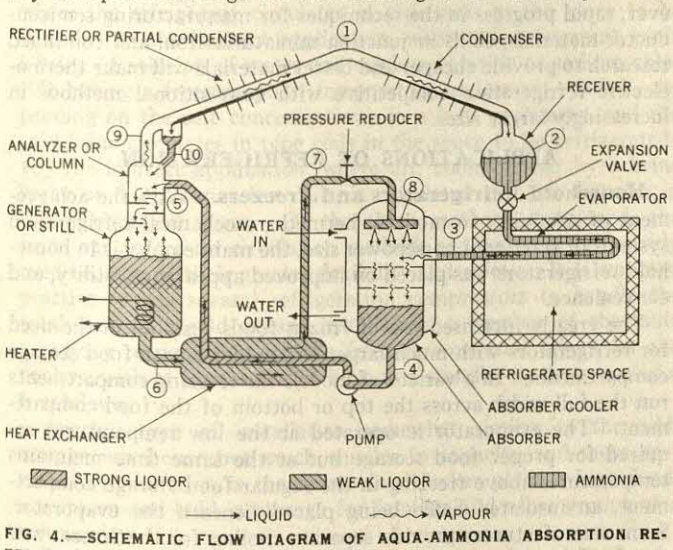

FIG. 4.—SCHEMATIC FLOW DIAGRAM OF AQUA-AMMONIA ABSORPTION REFRIGERATION CYCLE

strong liquor trickles down trays against a current of vapour of ammonia and water rising from the boiling solution in the generator below it. The heater (electric, gas, or low-pressure condensing steam) boils the ammonia-water liquor, and the hot vapour (about 220° F) rises up the analyzer counterflow to the cold strong liquor. As a result of this distillation process the vapour at the top of the analyzer (point 9) reaches a concentration of about 94%. This concentration is further increased as the vapour continues its way through the rectifier, where partial condensation takes place, and the vapour is enriched to about 99.5% ammonia as it enters the condenser at about 125° F (point 1). The small amount of condensate (about 60% ammonia) formed in the rectifier flows back to the top of the analyzer (point 10). As the liquor boils in the generator the part weak in ammonia gravitates to the bottom of the generator, whence it is taken to the absorber through a pressure reducer (point 7). On its way to the absorber this weak liquor is partly cooled in the heat exchanger as it heats up the strong liquor. The COP of absorption systems is much lower than that of mechanical refrigeration systems (about 0.5); however, this disadvantage is offset by the fact that they can be made to operate on inexpensive, low-grade energy. Also, the fact that they have no major moving parts makes for quiet and vibration-free operation, a feature desirable in some applications.

Electrolux Absorption Refrigeration System.—An ingenious modification of the absorption cycle shown in fig. 4 is the Electrolux absorption system, in which the refrigerant is taken around the refrigeration cycle without employing any machinery with moving parts. This system was invented in the early 1920s by two Swedish engineers, Carl Munters and Baltzar von Platen, while they were still undergraduates at the Royal Institute of Technology in Stockholm. The Electrolux system is in all respects identical to the ammonia-water absorption system with the exception that the strong-liquor pump, the expansion valve, and the pressure-reducer valve are all eliminated. In the Electrolux system the ammonia is transported from the absorber to the generator by going into solution in water, the aqua ammonia being circulated by gravity and thermal siphon effect. The functions of the expansion and pressure-reducer valves are performed by an inert atmosphere of hydrogen gas (insoluble in water or ammonia) that circulates between the evaporator and the absorber, transporting the ammonia vapour with it. Heat is supplied to the generator, forcing slugs of strong aqua-ammonia solution and its vapour into the standpipe and lifting the liquid in the same way a coffee percolator operates. As this stream discharges into the top of the generator the liquid and vapour separate, and the concentrated ammonia vapour enters the rectifier, where the concentration is increased by partial liquefaction prior to entering the condenser. The small amount of condensate formed in the rectifier returns to the top of the generator. The ammonia vapour is liquefied in the condenser and is discharged as a liquid into a flash chamber at the head of the evaporator. Hydrogen gas released in the absorber also enters the evaporator at this point, and as a result ammonia evaporates into this hydrogen, thus undergoing a drop in temperature. The evaporation of the ammonia is caused by its drop in pressure from about 180 psi in the condenser to a partial pressure of 30 psi in the evaporator. This is explained by a physical law discovered by John Dalton which states that the total pressure of a mixture of gases is equal to the sum of the pressures that each gas in the same volume and at the same temperature would exert if the other gases were absent. Therefore, when the ammonia which is liquefied at 180 psi in the condenser enters the evaporator, where the partial pressure of the hydrogen is only 150 psi, it evaporates at a rate to make up the difference between the two pressures; *i.e.*, 30 psi. The mixture of hydrogen gas and ammonia vapour leaves the evaporator and enters the absorber, where it meets a spray of weak aqua ammonia. Within the absorber the ammonia vapour is readily absorbed into solution by the weak aqua ammonia as it trickles down successive perforated trays and leaves the absorber at the bottom as strong liquor, while the inert hydrogen gas free of ammonia vapour rises up the absorber and leaves at the top to repeat its cycle. An absorber cooling jacket, in which water is circulated, is provided to remove the heat of solution generated by the absorption of ammonia vapour by the weak liquor. The strong liquor leaving the absorber proceeds to the generator, being partially heated on its way in the heat exchanger by the hot weak liquor coming from the generator on its way to the absorber. It is seen that in this system the total pressure in all its parts is the same (except for minor friction losses). While the partial pressure of the refrigerant varies from a minimum in the evaporator to a maximum in the condenser, a compensating variation in the partial pressure of the hydrogen gas enables the maintenance of the same total pressure throughout.

THERMOELECTRIC REFRIGERATION

The discovery of the phenomena of thermoelectricity dates back

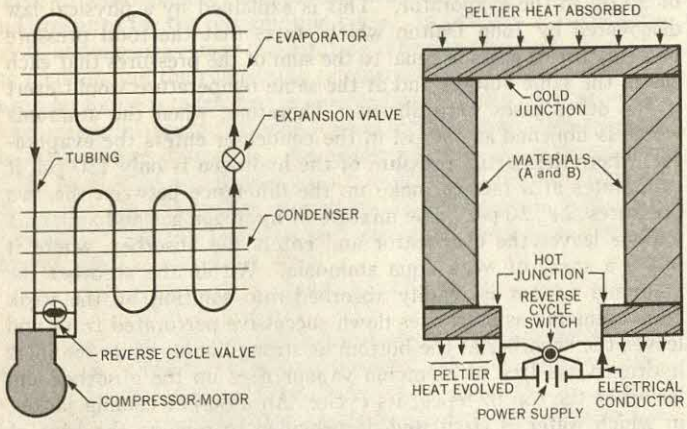
to 1821 when T. J. Seebeck first observed that in an electric circuit consisting of two dissimilar metals an electric current flowed in the circuit when the two junctions were maintained at different temperatures. In 1834, J. C. Peltier observed the reverse effect, namely, that if an electric current flowed across the junctions between two dissimilar metals, originally at uniform temperature, heat was either absorbed or generated at the junctions, depending on the direction of current flow and the nature of the two dissimilar metals. These cross-flow effects, namely, that an electric potential causes thermal energy to flow, and vice versa, did not receive serious consideration for heating or cooling applications because of the small magnitude of these effects in metals. In fact, until the mid-1940s the primary application of the Seebeck and Peltier effects was restricted to thermocouples as temperature measuring sensors.

The advent of semiconductor devices such as transistors stimulated research on semiconductor materials, which have much more pronounced Seebeck and Peltier effects than metals. A. F. Ioffe in the Soviet Union perhaps contributed more than anyone else to the understanding and popularization of thermoelectricity. He was among the first to realize the practical importance of semiconductors for thermoelectric cooling applications. As early as 1953, Ioffe and his associates at Leningrad built a laboratory model 0.35-cu.-ft. refrigerator that was maintained at 39° F in an environment at 80° F. From this point on, development of thermoelectric refrigerators and many other specialized cooling devices progressed rapidly, and in 1963 small-capacity household refrigeration appliances were marketed competitively in the U.S.

The effectiveness of a thermoelectric system is measured by a quantity referred to as the "Figure of Merit," Z, defined as

$$Z = \frac{(\alpha_{AB})^2}{(\sqrt{k_A \rho_A} + \sqrt{k_B \rho_B})^2} \qquad (7)$$

where α_{AB} is the relative Seebeck coefficient between the two thermoelectric elements; k is the thermal conductivity; and ρ is the electrical resistivity. The subscripts A and B refer to the two materials comprising the thermoelectric couple. While results of proprietary research in a rapidly developing field are not immediately divulged, one can safely assume that actual performance is always ahead of the known state of the art. In the early 1960s, representative figures for the above quantities were: $Z = 0.003/°C$; $\alpha = 0.0002$ v/°C; $\rho = 0.00083$ ohm-cm; $k = 0.016$ w/cm °C. Thermoelectric elements are commercially available which exhibit cooling to approximately −50° F from an ambient of 80° F with no applied heat load. This represents a temperature differential of 130° F.



COMPONENTS	COMPONENTS
EVAPORATOR	COLD JUNCTION
CONDENSER	HOT JUNCTION
COMPRESSOR-MOTOR	POWER SUPPLY
TUBING	ELECTRICAL CONDUCTOR
EXPANSION VALVE	ENERGY LEVEL DIFFERENCE BETWEEN ELEMENTS A AND B
CYCLE REVERSING VALVE	POLARITY REVERSING SWITCH
FUNCTIONS	**FUNCTIONS**
REFRIGERANT	ELECTRON GAS
MOTOR LOSSES	POWER SUPPLY LOSSES
COMPRESSOR LOSSES	THERMOELECTRIC ELEMENT LOSSES
CAPACITY MODULATION MECHANISM	CAPACITY MODULATION BY VARYING CIRCUIT CURRENT

FIG. 5.—ANALOGOUS COMPONENTS AND FUNCTIONS BETWEEN (LEFT) MECHANICAL REFRIGERATION CYCLE AND (RIGHT) THERMOELECTRIC REFRIGERATION CIRCUIT

Fig. 5 depicts the component counterparts and analogous functions between a mechanical vapour compression refrigeration system and a thermoelectric cooling circuit. It was indicated in the discussion of mechanical refrigeration systems that, in principle, the heating and cooling functions of the condenser and evaporator, respectively, could be interchanged by reversing the direction of refrigerant flow, but a closer examination of the mechanical equipment involved would indicate that such flow reversal would be difficult and costly. Another drawback of mechanical refrigeration systems is their drastic limitations with respect to miniaturization.

A thermoelectric circuit requires no moving parts. The conventional motor, compressor, condenser, expansion valve, evaporator, and refrigerant are replaced by one or more thermoelectric junctions and a power supply source. A simple reversal of the polarity of the power supply results in an interchange of the heating and cooling processes. Another important operational advantage is the simplicity with which the refrigeration capacity of a given unit can be modulated by simply varying the magnitude of the electric current flow through the thermoelectric junctions. The counterpart operation in the case of the mechanical refrigeration system would consist of varying the piston displacement, or the speed of the compressor, or otherwise controlling the flow of liquid refrigerant. It is also clear that a thermoelectric cooling system can be made in true miniature for special applications.

The primary disadvantage of the thermoelectric cooling system is economic. Although the situation is rapidly changing, the production of semiconductors and the fabrication processes of multiple-junction elements are expensive. This, together with high power requirements because of low thermodynamic effectiveness of the thermoelectric energy conversion, still prevents thermoelectric cooling from being competitive for major applications. However, rapid progress in the techniques for manufacturing semiconductor materials, skills in junction miniaturization, and continued research to provide cheaper and better materials will make thermoelectric refrigeration competitive with conventional methods in increasingly larger sizes.

APPLICATIONS OF REFRIGERATION

Household Refrigerators and Freezers.—With the achievement of reliability in modern, hermetic, mechanical refrigeration systems of fractional horsepower size, the main emphasis in household refrigerators was placed on improved appearance, utility, and convenience.

The greatly increased use of frozen foods resulted in the need for refrigerators with much larger and colder frozen-food storage compartments. In a variety of models the freezing compartments run the full width across the top or bottom of the food compartment. The evaporator is operated at the low temperatures required for proper food storage but at the same time maintains temperatures above freezing in the regular food storage compartment, an insulated baffle being placed beneath the evaporator. Some manufacturers provide separate cooling for the freezer and the food storage compartments with separate evaporators. In larger refrigerators an exterior two-door design was introduced, with the freezer and food storage compartments completely separated from each other. The volume of the frozen-food compartment may vary from 20 to 100% of the food storage compartment volume. Those in the latter category are normally classified as combination refrigerator-freezers.

The trend toward specialized interior designs has become a common practice. Meat storage compartments maintained at temperatures slightly above freezing, with relative humidities around 90%, special high-humidity compartments for leafy vegetables, shelves on the inner panel of the door for storage of small bottles, containers, eggs, etc., and compartments with provisions for maintaining butter at suitable spreading temperatures are common. An-

other important feature in modern household refrigerators is the rapid automatic defrosting of the evaporator. With defrosting cycles ranging from 5 to 30 min., no substantial rise occurs in the frozen-food temperature or in the normal food compartment temperature.

The use of household freezers in urban homes and on farms has constantly increased since they first assumed commercial importance in 1937. The household freezer provides a storage space at a temperature of 0° F or below and a fast-freezing zone where limited quantities of fresh food may be frozen in a reasonably short time with minimum disturbance of the stored load temperature. Modern freezer cabinets are made in two general styles, namely, the upright freezer and the chest-type freezer. Upright freezers have followed the pattern of household refrigerators, with interior locker doors that reduce air spillage and form convenient loading shelves when the main door is opened. Tests comparing chest and upright types indicate no significant difference in operating costs with a door-opening frequency of two per day. The frost accumulation in the upright type may become objectionable when more frequent door openings are necessary, but in household use this is rarely the case.

Cold-Storage Warehouses.—Cold-storage warehouses vary in capacity from 1,000,000 to 6,000,000 or more cubic feet of storage space devoted, on the average, two-thirds to freezer space and one-third to cooler space. Unless special provisions are made for quick freezing, the minimum temperatures maintained in these spaces usually are: sharp freezers, −15° to −10° F; carrying freezers, −10° to 0° F; and coolers, 30° F. The actual refrigeration capacity necessary to take care of a cold-storage warehouse is not always easy to estimate, as the load requirements vary appreciably with the nature of products stored and many other operating variables, including the size of the plant. To give an idea of the order of magnitude involved, one can say that an average cold-storage warehouse having 6,000,000 cu.ft. of storage capacity requires about 300 tons of refrigeration.

The cooling systems used in cold-storage applications come under three main classifications, namely: (1) the direct application, where the refrigerant circulates in pipe coils in the space to be cooled; (2) the indirect application, where the refrigerant cools a brine (a solution of water and calcium chloride or sodium chloride having a freezing point temperature as low as −60° F, depending on the salt concentration) in a heat exchanger, and the cold brine circulates in pipe coils in the space to be refrigerated; (3) the indirect application, where air, cooled either by a brine spray or direct expansion coils, is circulated through diffusers in the refrigerated space. Of the three methods mentioned, the brine and forced-air circulation methods are the most extensively used because of their greater flexibility and safety. It is common practice to use several refrigeration compressors to handle the total load of a cold-storage installation, a number of the units supplying refrigeration for the freezer rooms and others for the coolers, with at least one unit kept as a standby in the event of a breakdown.

Another type of installation somewhat similar to the cold-storage warehouse but much smaller in capacity and more specialized in function is the frozen-food locker plant, where foods are frozen and held in storage for families and other groups of a community.

Refrigerated Food Transportation.—*Trucks and Trailers.*—The distribution of refrigerated foods from major storage centres to retailers and even the long-distance hauling from farms and food processing centres to cities is handled to a large extent by refrigerated trucks and trailers. In the main, two types of truck bodies are constructed: those maintaining 35° to 40° F for carrying fresh meat, vegetables, and dairy products; and those maintaining about 0° F for ice cream and frozen foods. Numerous types of mechanical refrigeration systems are used in both trucks and trailers, the source of power being obtained either by a separate internal-combustion engine or from the truck engine itself, either by a crankshaft extension at the front end or by a power take-off from the transmission. Besides mechanical refrigeration, water ice and dry ice (solid carbon dioxide) are extensively used in refrigerated transportation. These are charged in conveniently located bunkers either at the end or near the ceiling of the truck body, and air is circulated past them and through the body by means of a small blower. The use of dry ice in refrigerated transportation (truck, trailer, and rail) was steadily increasing in the 1960s despite its much higher cost per pound. Its low temperature makes it ideal for frozen-food transportation, and when it is used for fresh foods the carbon dioxide gas in the atmosphere immediately surrounding the product serves to reduce the oxygen content of the air, thus minimizing possible deterioration resulting from oxidation. Also, it inhibits the growth and development of bacteria and various molds that cause spoilage. It is often the practice to precool the interior of the truck, as well as the fresh produce, prior to or at the time of loading.

Refrigerated Railway Cars.—Despite the tremendous volume of perishables transported by trucks and trailers and their increasing competition with the railways, the main bulk of long-distance refrigerated transportation was handled by rail in the 1960s. The earliest known use of refrigeration by the railroads was in July 1851, when several tons of butter were shipped from Ogdensburg, N.Y., to Boston, Mass., in a wooden boxcar insulated with sawdust and stocked with ice. More than a century later, water ice was still more or less the universal cooling medium in refrigerated freight and express cars. The modern standard refrigerator car in the U.S. is 40 ft. long and of the end-bunker type, equipped with fans and having about 4 in. of insulation. Some cars are 50 ft. long and have 6 in. of insulation, using 30% by weight of sodium chloride salt with water ice to provide a bunker temperature of −3° F for frozen foods. The use of mechanical refrigeration on railways was still more or less in the developmental stage in the early 1960s. Considerations of high first cost and high maintenance costs were expected to delay wide-scale mechanical installations. The few mechanically refrigerated freight cars in operation were mostly equipped with Freon-12 compressors run by diesel-electric drives. Each of these cars had a refrigeration capacity of about seven tons, and they were used mainly by the frozen-food and frozen-concentrate industry.

Marine Refrigeration.—In the summer of 1880 the steamer "Strathleven" brought to England the first successfully carried refrigerated meat cargo. Early shipboard installations were equipped with dense-air machines, later being replaced by carbon dioxide and ammonia systems. In modern installations Freon refrigerants are used extensively. Design conditions and other basic principles are not greatly different in marine refrigeration from those in cold-storage warehouse practice. All equipment and installations must specify compliance with the rules and regulations of various classification societies (*e.g.*, American Bureau of Shipping, or *Lloyd's Register*, or both, etc.).

Manufacture of Water Ice.—Despite the tremendous increase in the use of fractional-horsepower mechanical refrigeration units for household and other commercial uses, the manufacture of water ice remained a major industry. The method most extensively used is the can method, using treated or untreated raw (tap) water. Galvanized steel ice cans, usually of about 320 lb. capacity, 11 × 12 in. at the top and 50 in. in depth, with an overall taper of ½ in. in their length, are submerged in a well-insulated (10- to 12-in. granulated cork) tank in which cold brine is circulated. Tank depths are usually about 52 in. for 320-lb. ice cans, and width and length seldom exceed 40 and 120 ft. The brine is cooled by direct-expansion evaporator coils normally placed between rows of cans. The velocity of the brine flowing past the cans and the brine temperature determine the time required for freezing. Brine velocities should not exceed about 35 ft. per minute, and variations of temperature should be kept less than 1° F.

For a given brine velocity, the time required to freeze a given thickness of ice is determined first by the brine temperature. As most raw waters, treated or untreated, crack upon freezing at temperatures below 10° F, the freezing temperatures are generally somewhat above this figure. The rate of freezing drops rapidly as the ice becomes thicker. An 11 × 12-in. can holding 320 lb. of water in 12° F brine takes 24 hr. to freeze the first 280 lb. of ice

and an additional 14 hr. to freeze the last 40 lb. When raw water is used to manufacture ice it is necessary to agitate the water in the cans during freezing to obtain clear ice. This is done by bubbling dry air, usually at about 15 to 18 psi gauge pressure, at the centre of each can, thus rejecting most of the dissolved minerals into the unfrozen centre core. When the water is almost frozen, the concentrated core, consisting of about three to four gallons, is sucked out and replaced with chilled fresh water to complete the freezing of the entire block. The amount of refrigeration required to manufacture ice depends on many factors, such as initial water temperature, brine temperature, insulation of brine tank, efficiency of refrigeration compressors, size of plant, etc. A good figure for a well-constructed plant of 30- to 50-ton daily ice capacity using 60° F water and 12° F brine is 1.52 tons of refrigeration per ton of ice.

Despite the large amount of ice consumption in all countries of the world, the methods for handling and processing ice have not changed significantly over the years. Only in the decade following World War II did mechanization of ice making become widespread. There was then a definite trend toward increased sales of ice in small sizes (cubed, crushed, sized, and shaved) aside from the manufacture of block ice. Installations of scoring, cubing, sizing, and packing machines for automatic vending stations expanded rapidly.

Comfort Air Conditioning.—In its strictest definition, comfort air conditioning must incorporate the following features: control of temperature, humidity, air distribution (ventilation), odour, air cleanliness, and in some instances air sterilization. All comfort air-conditioning applications are functionally similar, whether the space under consideration is that of a residential dwelling or that of a large building. In large installations, involving sometimes 1,000 or more tons of refrigeration capacity, the central system design is adapted. However, most smaller installations run in sizes from ½ ton for window air-conditioning units to 5, 10, or 25 tons for small retail shops, restaurants, etc. (*See* AIR CONDITIONING.)

Other Applications.—The following constitutes only a partial illustrative list of the many diverse applications where refrigeration is used extensively: food processing and manufacturing of dairy products (butter, ice cream, cheese), beverages (beer, wine, and other alcoholic and carbonated beverages), bakery goods, etc.; industrial and engineering applications for liquefied storage and transportation of industrial gases (oxygen, nitrogen, hydrogen), manufacture of dry ice, synthetic and natural yarn processing and weaving in the textile industry, petroleum refining and chemical processes, metallurgical processes, engineering construction (freezing of sliding silty soils in the construction of dams, tunnels, shaft sinking, curing of large masses of poured concrete), low-temperature testing facilities, wind-tunnel cooling, etc.; industrial air conditioning for printing and paper manufacture, precision machining and assembly of metal machine parts, confectionery processing, deep-mine cooling, and preservation of valuable books, paintings, and tapestries in libraries and museums.

See AIR CONDITIONING; HEATING AND VENTILATION; LOW-TEMPERATURE PHYSICS; *see* also references under "Refrigeration" in the Index.

REFUGEES, persons who have fled from one place to another to escape persecution or danger, usually during time of war or political upheaval. Discrimination against particular racial, religious, or political groups has historically developed into threats to life and liberty, precipitating the flight of refugees, in many instances across national boundaries and without guarantee of asylum. Changes in national boundaries, postwar agreements, and the actions of aggressor states have also resulted in transfers or exchanges of populations, generally of minority groups, with or without the transfer of their possessions. Notable examples from early modern history are the Moors and Jews who were expelled from Spain, the Huguenot refugees in 16th-century France, some of the early settlers in America, the Loyalists who fled to Canada during the American Revolution, and the émigrés of the French Revolution.

After a period of relative subsidence during the 19th century, the refugee problem emerged again on a vast scale in the 20th century with the rise of Communism and Fascism and the occurrence of two wars of worldwide scope. In some cases the refugee movements were only temporary. For example, although the Belgian refugees who fled from the German invaders in 1914 were numerous, they did not attempt to create a new life or to establish new homes outside their native land; their migration was only temporary, like that of the refugees who fled from the invaded provinces of France, Italy, and Rumania, and to a smaller extent from all the territories occupied by enemy troops during World War I. But in other cases, great masses of war refugees had little prospect of ever returning to their homes or of recreating their previous life there. This was the case with Jews and others who fled from Hitler's Germany and of countless thousands who were uprooted during and after World War II.

Before the 20th century, refugees attempting to escape from oppression and to found new homes did not meet with insuperable obstacles. What distinguishes the 20th-century refugees is the increasing difficulty of fleeing and, even more important, the immense difficulty, often impossibility, of gaining entrance elsewhere. The rise of modern totalitarianism, especially in Nazi Germany and Soviet Russia, brought in its train the closing of national boundaries, and the problem of getting in became as great as the problem of getting out. The result was the stateless refugee, shunted from border to border, dependent on charity and chance rather than law, a modern "man without a country."

From the Russian Revolution to World War II.—The first massive refugee movement of the 20th century was caused by the Russian Revolution of 1917. During the post-Revolutionary struggles of the Soviet government, 1,500,000 enemies of the new regime were forced into exile. Scattered throughout France, Germany, the borderlands of the Soviet Union, and parts of the Far East, these exiles hoped that the Soviet experiment would fail and that they would then be able to return to their homes. During the 1920s approximately 200,000 Armenian and 500,000 Greek refugees fled from Turkey and 100,000 Bulgarian refugees left their homes because of Bulgaria's territorial cessions to neighbouring countries after World War I.

In 1920 the League of Nations appointed Fridtjof Nansen (*q.v.*) as the first high commissioner for refugees. For the next ten years, until his death in 1930, this man was the main, almost the only, bulwark between these refugees and oblivion. Nansen's first attack upon the problem was the Nansen passport, an identity document that was recognized in lieu of a passport by 28 governments as a result of tireless prodding by the high commissioner. Even more important, Nansen constantly prodded governments to lower their immigration barriers. The twin enemies of the high commissioner were international apathy and a chronic shortage of funds. Nevertheless, the Nansen office managed to integrate close to one-third of the post-World War I refugees into over 20 European countries.

Nansen's death preceded by only three years the ascent to power of Adolf Hitler in Germany. Until 1939 the policy of the Nazi government was to rob the Jews and then to let them go. When they attempted to migrate the Jews met resistance almost everywhere and only a small minority found refuge before the policy of annihilation began in earnest in 1940. Indeed, Adolf Eichmann, speaking in his defense at the Jerusalem trial, claimed that the so-called final solution (mass execution) of European Jews had been made possible by the resistance to Jewish immigration all over the world. The well-known impotence of the Nansen office during the 1930s was part of the general decline of the League of Nations.

World War II.—The outbreak of World War II merged the tragedy of the Jewish people into the greater tragedy of worldwide military conflict. The mass movements set in motion by the expansionist policies of the Axis powers eclipsed all previous human floods in history.

While Hitler's Germany was experiencing its early successes, millions of refugees fled before the advancing Nazi armies. Following the German conquest of Poland in September 1939, 300,000 Poles sought sanctuary within the frontiers of the Soviet Union. As the blitzkrieg continued throughout 1940, and the Netherlands, Luxembourg, Belgium, and northern France were overrun, an avalanche of over 5,000,000 desperate refugees swept into southern France, only to be overtaken by the Germans in November 1942. When the Germans launched their Balkan campaign in April 1941, 300,000 refugees chose homelessness rather than life under Nazi rule. Finally, when Hitler attacked the Soviet Union in June 1941, a seemingly endless stream of fugitives from the eastern borderlands sought refuge in the vast spaces of inner Russia. It has been estimated that over 12,000,000 people were made homeless by the advancing Nazi armies.

Mass refugee movements were not limited to the European continent. Germany's Asian partner, Japan, embarked upon her own aggressive course and drove over 30,000,000 Chinese from their homes. When the Japanese conquest spread southward to Burma, the Malay states, the Philippines, and Indochina, more refugees fled from the approaching armies. By 1943, when the Axis forces had attained their greatest territorial expansion, approximately 60,000,000 human beings had been displaced from their homes throughout the world.

When the fortunes of war turned in 1943 and the Soviet armies began to push back the German invaders, the 12,000,000 displaced Russians who had sought sanctuary in the inner recesses of the Soviet Union followed in the wake of the Red Army. As Japan's expansion was checked in 1942–43, Chinese refugees began to return to their former homes. Unlike their brethren in Europe, the Chinese displaced persons had not moved over long distances, but for the most part had hidden in the neighbouring hills of the Chinese countryside and thus found it easier to return to their homes as the Japanese retreated. They returned to a gutted land and a broken economy, however, and faced as difficult a time as the European refugees.

Post-World War II Problems and Policies.—The first concerted attempt to deal with the post-World War II refugees was made through the United Nations Relief and Rehabilitation Administration (UNRRA). UNRRA was set up by 44 nations in 1943 while the sense of cooperation and urgency was still strong among the Allies. The main task of UNRRA was to be the repatriation of uprooted refugees. In this job it was largely successful but in 1945 more than 1,000,000 refugees living in almost 1,000 camps in Germany, Austria, and Italy refused to be repatriated. Mostly nationals of countries that had come under Soviet rule, they were strongly anti-Communist in outlook and were devoted to their own national states. Rather than live under Communism, they wished to settle in new homes. Because of the special problem they posed, the United Nations created a new agency to deal with them—the International Refugee Organization (IRO; *q.v.*).

The IRO operated between 1947 and 1952 and was the only refugee agency to deal with all aspects of the problem, including legal protection, rehabilitation, and resettlement. Within these years IRO successfully completed the greatest overseas resettlement scheme for refugees in history. It provided food, shelter, medical care, and vocational instruction in all its camps and then prodded governments to send selection missions to the camps and to relax their restrictive immigration laws. The United States, for example, passed the Displaced Persons Act in 1948; under this and later acts 395,000 refugees were admitted. When the IRO went out of existence in 1952, over 1,000,000 people had been resettled in 80 different lands.

Unfortunately, during the lifetime of IRO, the floodtide of human intolerance had not abated. For every refugee resettled by IRO, 25 new ones had been created. The partition of the Indian subcontinent in 1947 precipitated a fratricidal conflict between Hindus and Muslims which resulted in a mass migration of millions of people. The outburst of violence accompanying the creation of the state of Israel sent almost 1,000,000 Arab refugees into the Gaza Strip, Jordan, Lebanon, Syria, and Iraq. The Korean War created almost 9,000,000 refugees from both North and South Korea. The German-speaking minorities (*Volksdeutsche*) expelled from the eastern provinces as a result of the Potsdam agreement numbered close to 8,000,000. Finally, a steady influx of refugees from Communist-occupied areas to the West took place. Hence the IRO, which had aimed at a complete solution of a temporary problem, succeeded only in achieving a partial solution of a permanent problem.

After the demise of IRO, the numbers of the uprooted increased even more. The Hungarian Revolution of 1956 ended in a mass exodus of about 160,000 refugees. Refugees from mainland China added over 1,000,000 refugees to the population of the British crown colony of Hong Kong. The crushing of Tibet by the Chinese Communists created a wave of refugees from that area. In the 1960s the United States received many refugees from Cuba, where Fidel Castro had established a Communist-oriented regime. In 1965 the U.S. government agreed to provide air transportation of from 3,000 to 4,000 Cuban refugees per month. Unrest in Africa brought the refugee problem to that continent as well. When Algeria gained independence in 1962, a large number of French settlers sought refuge in France. In 1963, 150,000 persons left Angola and settled in the Republic of Congo (Léopoldville), and nearly the same number went from Rwanda to neighbouring countries. Thousands were displaced by civil strife in the Congo during 1965. The conflict in Vietnam had added approximately 1,000,000 refugees by 1966, consisting of defectors from North Vietnam who had fled to South Vietnam as well as of South Vietnamese villagers displaced as a result of the war.

The response of the world community to the refugee problem after the demise of the IRO was sporadic and divided. Two agencies were created to operate under the aegis of the United Nations. First, the Office of United Nations High Commissioner for Refugees (UNHCR) was established in 1950 to deal with the world refugee problem in general. Suffering from a chronic lack of funds, the commissioner, like his predecessor under the League, was dependent almost exclusively on voluntary contributions from governments and private sources. These funds made it possible to clear the European camps by 1960 and to give a measure of assistance to the Chinese refugees in Hong Kong. The second UN refugee organ was the United Nations Relief and Works Agency for Palestine Refugees in the Near East (UNRWA), established in 1949, which fought a valiant battle to reintegrate Arab refugees, swollen in numbers to well over 1,000,000 by 1965, in the lands surrounding Israel within the framework of general regional development. In view of the Arabs' continued insistence upon their return to Israel and the Israelis' equally adamant refusal to readmit them, no permanent solution was in sight.

Two other governmental refugee organs not under United Nations authority are worthy of note. First, the Intergovernmental Committee for European Migration (ICEM) was established in 1951 to alleviate surplus population problems in Europe. Second, the United States Escapee Program (USEP) helped Hungarian refugees to immigrate to the United States.

The services to refugees and displaced persons rendered by the two United Nations agencies and by individual governments are supplemented by those of numerous voluntary agencies. In the United States alone there were nearly 40 such agencies in the 1960s. Generally, these agencies were related to welfare organizations sponsored by various church groups or nationally organized welfare services. The Red Cross, CARE, and the United States Committee for Refugees were typical examples. Governmental bodies came to depend very heavily on such voluntary agencies.

Finally, private individuals took the initiative in working to alleviate the world refugee problem. In 1959 three young Englishmen proposed that the period July 1, 1959, through June 30, 1960, be designated as World Refugee Year (WRY). The idea caught hold and the UN General Assembly supported the proposal in a resolution passed on Dec. 5, 1958. The record of WRY was marked by both successes and failures. On the positive side, 97 countries and territories participated; financial contributions and pledges totaled over $80,000,000; resettlement opportunities for refugees were increased; and Austria, West Germany, Belgium, the Netherlands, Luxembourg, Italy, and Australia enacted measures

to improve the refugees' status. On the debit side, the year made no significant difference to the Arab refugees in the Middle East and the Chinese refugees in Hong Kong. Indeed, human intolerance created new waves of displaced persons during the year. As a result, the question arose in several countries whether World Refugee Year should be extended or made a permanent institution.

One conclusion that may be drawn from the study of the refugee problem is that so long as human intolerance exists, and so long as such intolerance remains primarily within the domestic jurisdiction of states, so long will there be refugees and displaced persons. Hence the refugee will probably remain a more or less permanent phenomenon. The world community has not recognized this truth, with the result that, parading through the annals of refugee history, there has been a permanent procession of temporary agencies. Intolerance produces refugees, and indifference is the major obstacle to a solution. This indifference has been manifested in the fact that states have been financially very tight-fisted toward refugee agencies, most of which were mendicants on the international scene, moving with hat in hand from government to government before finally being starved out of existence.

It is a tragic commentary on our times that the century of the United Nations should also be the century of the homeless man. Today, the community of exiles confronts the community of nations. Human rights have become virtually identical with national rights. The twin solutions to the refugee problem would be policies of greater openness toward immigration and a concerted attack upon the problem by a permanent body, patterned on the model of the International Refugee Organization.

For current developments, see *Britannica Book of the Year.*

REFUSE DISPOSAL is the term employed in the United States and Canada for the collection and disposal of the solid wastes of a community, including garbage, rubbish and ashes. In Great Britain this type of refuse is called dry or town refuse, as differentiated from wet refuse (fecal matter) and mixed refuse (a mixture of town refuse and fecal matter).

Garbage is the waste matter resulting from the preparation and consumption of food; rubbish is all nonputrescible solid wastes, except ashes, including both combustible and noncombustible material such as paper, rags, wood, plastic and metals.

Sanitary refuse disposal is essential to community health. Refuse has been shown to be important as a breeding ground or food source for rats, flies and other potential carriers of diseases of man. It has been demonstrated to be of importance in the transmission of trichinosis of man and vesicular exanthema, foot-and-mouth disease, cholera and other diseases of swine. Rubbish has been found to be a significant factor in the incidence of building fires in the United States. Particulate matter and smoke from the burning of refuse can be a significant source of atmospheric pollution, while improper disposal has sometimes resulted in surface- and ground-water pollution. Potential nuisance factors, such as smoke and odours resulting from open dumps, are well recognized.

Refuse disposal consists of three phases: storage on the premises, collection for transport to the final disposal site and final disposal.

Quantity of Refuse.—A household of four people in an American community may be expected to produce an average of 70 lb. of refuse each week, or about 2½ lb. per capita per day. If commercial garbage and rubbish, incinerator ash and solid industrial wastes are included, over 4 lb. of refuse per capita per day may be expected from a community-wide collection system. In England about 672 lb. per capita per annum is considered average. In U.S. and Canadian communities where the refuse has a negligible ash content, garbage has been found to comprise as little as 20%–25% of the refuse by weight, with the remainder rubbish. Garbage has a moisture content of 60%–70%. The moisture content of rubbish usually approximates 25%–35% of its over-all weight.

Premises Storage.—Most cities require that household garbage be well wrapped and stored in durable, easily cleaned containers with tight-fitting covers. Glass or metal food containers should be stored in similar receptacles. Other rubbish may be tied in easily handled bundles or so placed in boxes that it will not cause littering or fire hazard. Ashes should be stored in metal containers. In most U.S. cities household refuse containers ordinarily are not permitted to exceed 26–30 gal. in capacity.

Collection of Refuse.—Methods of collection vary. Garbage may be collected separately from the other refuse; in mixed collection, garbage and rubbish—or sometimes garbage, rubbish and ashes—are collected at one time and from a common receptacle. The trend is toward mixed collection. Separate collection is utilized when garbage is used for feeding to swine or is ground and disposed of in the sewerage system, or when cheaper methods are at hand to dispose of the less objectionable components of the refuse.

Where garbage is collected separately, it is the usual practice to collect it twice a week in the summer and once or twice a week in the winter. A few cities collect more frequently. Most make daily collections in the business sections. Most of the large cities and about half the smaller ones in the U.S. employ municipal collection, contract or private collection being used otherwise.

Collection Equipment.—There is nothing that could be called a standard type of refuse collection vehicle. In America municipal garbage-hauling vehicles are usually custom-designed. Enclosed mixed-refuse collection vehicles are equipped with mechanically or hydraulically operated packing devices to compress the voluminous refuse and thereby increase the amount the vehicle can accommodate. Many industries and other concentrated production areas use large portable containers which when full are transported to the disposal site by a vehicle equipped with a special hoist.

Disposal.—There are five methods of refuse disposal: reclamation for re-use (although this disposes only of certain components in the refuse); disposal into the sewerage system; incineration; dumping in water; and disposal on land.

Reclamation.—In its simplest form reclamation is the removal of such items as paper or heavy metals for salvage. In Great Britain this is practised in many cities in separation plants constructed for the purpose. In America reclamation is usually carried on as private enterprise, either by the individual householder or by contract arrangement at the disposal site. Metals from incinerator ash and the ash itself are often used for salvage or reclamation purposes.

Feeding waste food to pigs has long been a popular method of garbage disposal because it is relatively cheap and often can be carried on by private enterprise at a profit, thus relieving the authorities of the responsibility and expense of garbage disposal. In Great Britain and Canada it has been required for many years that garbage fed to swine be cooked to disinfect it and to prevent possible spread of disease. In the United States, vesicular exanthema, a disease of swine similar to foot-and-mouth disease and spread primarily by the practice of feeding raw garbage, became epizootic in the early 1950s. By 1960 all of the states had adopted legislation or regulations requiring the disinfection (usually by cooking) of garbage fed to pigs. Although the use of residential garbage in the U.S. for pig food has declined substantially, use of commercial garbage from hotels and restaurants is widespread.

Composting is the biochemical alteration of refuse from a noxious to an innocuous usable humus. During the first half of the 20th century a number of anaerobic and aerobic processing schemes were offered under various proprietary names. None was successfully employed in the United States on a continuing basis, primarily for economic reasons.

Composting of refuse has been successfully carried on in the

Netherlands and the Jersey Islands for many years. The method has also been used with some success in Great Britain, France, New Zealand and India.

Reduction, or the cooking of garbage to remove salvable greases and fats for industrial use and to produce tankage usable as an animal food base, was a recognized method of reclamation in the United States in the first quarter of the 20th century. The introduction of detergents, which reduced the demand for fats in soap manufacture, together with increased labour costs, made this method uneconomical, and the last municipal garbage reduction plant ceased operation in the early 1950s.

Disposal Into Sewerage System.—If garbage is ground into minute particles it can be discharged into the community sewerage system. Millions of household grinder units were installed in the United States following their introduction in the early 1930s. Little difficulty is encountered in a properly designed sewer system as a result of this practice, and household water consumption will increase only 1% to 2% with the installation of a grinder. Increases in solids handling capacities are needed at the sewage treatment plants in cities where large numbers of grinders have been placed in service, however, and for this reason some communities with already overloaded treatment plants had to forbid their use. A few cities having separate garbage collection systems used central grinding stations at which truckloads of garbage could be handled at one time.

Most newly constructed food-handling establishments in the United States, particularly hospitals and other institutions, have kitchens equipped with food waste grinders. The grinding of garbage is an important sanitation device since it eliminates the need for storage and collection of the most noisome and potentially hazardous portion of community refuse.

Incineration.—The burning of community refuse is one of the safest and most efficient methods of disposal, provided it is properly done. The special equipment and methods essential to this process are described in the article INCINERATOR.

Dumping in Water.—For many years the disposal of refuse in large bodies of water was an accepted practice. The refuse from a number of large cities was taken to sea on barges and dumped. Unfortunately, much of the lighter material found its way back to the beaches with the wind and the tides.

New York city was prohibited from continuing this practice in 1936 as the result of a ruling by the U.S. supreme court. Very few cities in North America or Europe resort to this method of refuse disposal.

Disposal on Land.—The indiscriminate dumping of refuse on land is an age-old practice still widely followed, particularly in small communities. However, the unsightliness of dumping grounds and the unavoidable presence of flies, rats, smoke and odours led to the development of more efficient and sanitary methods.

TRENCH METHOD OF SANITARY LAND FILL USED TO DISPOSE OF REFUSE IN A FLAT LAND AREA

The method of controlled tipping, known in the U.S. as sanitary land fill, was introduced in England in 1912; it makes use of the natural fermentation brought about by microorganisms in the putrescible portion of the refuse. Usually the refuse is deposited in shallow layers, compacted, and covered within 24 hours with compacted earth or other chemically inert material to form an effective seal. Mechanical equipment such as a bulldozer mounted on a heavy tractor is used to grade, compact and cover the refuse. The method often is employed to reclaim otherwise useless land and by the early 1960s was used by over 1,400 American communities. *See* also SEWAGE DISPOSAL.

REGAL, a small bellows-blown keyboard instrument popular during the 16th and 17th centuries. Its sound is produced by beating reeds which have either no resonators or very short resonators. The reeds are placed immediately behind the keys and the two hand-blown bellows are placed horizontally behind the reeds. One form of the instrument, the bible regal, can be folded up when not in use and when closed resembles a large book. Several regals are mentioned in the inventories of Henry VIII's effects; in addition to the reeds some of these had a "cymbal" stop, presumably a very small mixture.

The regal's highly coloured buzzing tone made it especially suitable for accompanying brass instruments, and in this context it is specified by Claudio Monteverdi as one of the several continuo instruments in his opera *Orfeo* (1607).

The term "regal" is also used for a type of reed stop in 16th–18th-century organs. These have beating reeds and small resonators, often of peculiar shape, which give a very colourful tone; such stops were revived on the continent in the mid-20th century. The modern *vox humana* stop is, in effect, a regal. (CE. C.)

REGATTA: *see* ROWING; YACHTING; BOATING.

RÉGENCE STYLE is the designation for the French art of the period from 1715 to 1730; it did not quite coincide with the regency of Philippe d'Orléans, duc d'Orléans (1715–23), between the reigns of Louis XIV and Louis XV. The *régence* style marked the transition from the massive, serious baroque art (*q.v.*) to the more elegant, lighthearted rococo style.

The term should not be confused with the English Regency (1811–20) during the latter part of the reign of George III. (WM. F.)

REGENERATION is the process by which organisms replace structures or organs which have been lost by accident or mutilation. This definition is not quite adequate because it does not cover two phenomena which belong undoubtedly to the category of regeneration phenomena. In some invertebrates, such as the fresh-water polyp *Hydra,* the planarian flatworm *Dugesia* and the starfish, a small fragment of the body can restore a complete, whole organism rather than merely an organ. Furthermore, many animals can restore structures lost in the normal course of life rather than by accident. The periodic molting of feathers in birds, the shedding of fur in mammals, of the exoskeleton in arthropods and of the epidermal scales in reptiles are followed by regeneration of the discarded structures. The uppermost cornified skin layers in mammals including man are constantly worn off in small bits and replaced by active, proliferating cell layers in the deeper layers of the skin. The same holds for the continuous replacement of hair, nails and claws. The teeth are replaced only once in mammals, including man, but there is a continuous succession of teeth in lower forms, such as the dogfish and shark. The antlers of deer are shed at regular intervals and then regenerated. The periodic changes in the genital tracts of female mammals during menstruation and oestrus also should be included here. All these instances in which replacements are part of the normal life functions are called physiological or repetitive regeneration, in distinction to restorative or reparative regeneration which follows injury. This article deals primarily with the latter type.

CAPACITY FOR REGENERATION

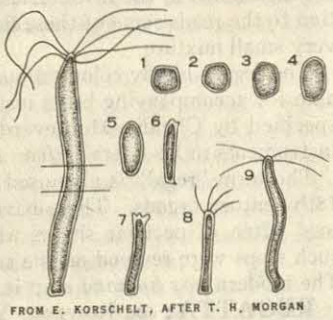
There are wide differences in the regenerative capacity of different animals. The one extreme is represented by the abovementioned invertebrates, in which a part of the body can restore

a whole organism. In higher organisms, as for instance the salamanders among the vertebrates, and many crustaceans and insects, only single organs, such as limbs, can regenerate; mammals cannot restore entire organs, but they can repair damage to tissues, such as bone fractures, skin and muscle injuries and peripheral nerve loss. These phenomena of tissue repair are, of course, included under the general heading regeneration.

General Types.—Regeneration can be accomplished in two ways: (1) by outgrowth of new tissue from the wound surface or (2) by the transformation and reorganization of the remaining parts, without an outgrowth of new material.

Where new tissue is produced, a regeneration bud, or blastema, is formed at the wound surface (*see* below, *Regeneration Process: Blastema Formation*). It is usually cone-shaped and consists of cells of an embryonic type, which gradually form the adult structures by processes of cell differentiation and growth, much in the fashion of embryonic development. The regeneration of limbs and tails in salamanders is an example of this type of regeneration, which T. H. Morgan termed epimorphosis.

The second type of regeneration, the remodeling of old parts, is called morphallaxis (fig. 1). Very small fragments of a freshwater or marine polyp, or of a planarian, undergo a change in shape instead of growing blastemas; they break down old structures, and build in their place new ones of a smaller proportion. All regeneration processes in protozoans are of this type. Occasionally, both types of regeneration take place simultaneously, and there may be no fundamental difference between them. The term regeneration is almost universally adopted as the all-inclusive term, with "epimorphosis" and "morphallaxis" as subheadings. C. M. Child (1941) proposed "reconstitution" as the general term to cover all related phenomena. He used the term regeneration in a narrow sense, synonymously with epimorphosis, as reconstitution by outgrowth, and the term reorganization as reconstitution by internal changes.



FROM E. KORSCHELT, AFTER T. H. MORGAN

FIG. 1.—REGENERATION IN THE FRESH-WATER POLYP HYDRA. THE SHORT PIECE BETWEEN THE TWO LINES (AT LEFT) REGENERATES INTO A NEW POLYP. 1 TO 9 ARE STAGES IN THE REGENERATION PROCESS

The aim of regeneration is to maintain or restore the fitness of an organism after the loss of parts. This aim is best accomplished by a replacement of precisely those structures which were lost. However, a number of cases are known in which more than, or less than, the lost part is regenerated, and other cases in which the regenerate is structurally different from the lost part. The term heteromorphosis covers all types of atypical regeneration. The term homeosis is used for those atypical regenerations in which the regenerate represents an organ different from the original. For instance, in crabs, an amputated eyestalk, under certain conditions, will be replaced by an antenna. Another type of atypical regeneration has been given special attention; namely, those instances in which the polarity of the regenerate is changed. For example, the posterior cut surface of a piece of planarian, under certain conditions, will regenerate a head instead of a tail. This type of polarity change is called polar heteromorphosis.

Theoretical Considerations.—When a regeneration blastema differentiates into the head of a planarian or into the limb of a salamander, the processes which go on in the blastema are fundamentally of the same nature as the embryonic developmental processes which created these organs originally. Although the regeneration processes are rarely exact replicas of the corresponding developmental processes, they are alike in some fundamental aspects. Both require a building material of plastic, undifferentiated, embryonic-type cells, and a set of specific organizing factors which direct and control the molding and differentiation of such building materials. In this sense, regeneration can be defined as the revival, or reactivation, of developmental potencies in organisms which have passed the embryonic stages of development.

If this point of view is adopted, then the close affinity of regeneration processes with asexual reproduction becomes evident. In fact, in some instances it is difficult to draw the line between the two. For instance, most protozoans reproduce asexually, by fission. The daughter individuals restore by regeneration those structures which they do not contain at the start of the fission. If a protozoan is cut in two by a fine instrument, the result is the same—each half regenerates the missing structures. In this instance, fission and regeneration differ primarily in the factors which set the processes in motion. Similarly, some flatworms and annelids (segmented worms) which possess high regenerative powers reproduce regularly by transverse fission or by a budding process at their posterior ends. Their regenerative potencies are placed, so to speak, in the service of reproduction. Budding is a mode of asexual reproduction particularly common among colonial forms. It is practised by coelenterates and tunicates among animals and by plants. A bud is an outgrowth on an adult organism which is an expression of the revival of growth potentialities at a localized area of the body. The parallel to regeneration is obvious. In many marine coelenterates a lateral regeneration bud can be produced easily by making a cut in the body wall. Again, the main difference between regeneration and spontaneous budding lies in the initiating stimuli.

If the ability for regeneration is considered as a residual developmental capacity which a number of organisms retain throughout adult life, it is implied that regeneration is the manifestation of a universal property of all organisms; namely, the capacity for growth and development. This point of view, now generally adopted, did not always prevail. It was seriously contested during the second half of the 19th century. Under the influence of the theory of natural selection, another theory of regeneration was strongly advocated by August Weismann and others. This theory emphasized the usefulness and adaptive value of regeneration; it stressed the point that regeneration was apparently limited to those organs and structures which are particularly in danger of being injured or mutilated by enemy attacks. It was assumed, therefore, that regeneration is not part of a basic equipment of all organisms, but is acquired secondarily as a special adaptation wherever the ability to regenerate is of crucial survival value in the struggle for existence. It was held that natural selection is instrumental in creating and improving the regenerative capacity. A just objection has been raised against this theory, namely, that in many instances inner organs regenerate which are not liable to injuries, as for instance, the crystalline lens of the amphibian eye, or the liver. For this and other reasons, Weismann's theory in its extreme form is untenable. However, its valid element, the emphasis on natural selection as a mechanism for increasing preexisting limited regenerative capacity, can be readily incorporated in the residual growth theory of regeneration.

Generally speaking, lower organisms have a better regenerative power than do higher organisms, but the regenerative capacity is distributed sporadically among animals and in many instances closely related forms differ widely in their regenerative capacity. A theory of regeneration has to explain this scattered distribution of regeneration. Natural selection cannot account for it, because there is apparently no close correlation between liability to injury and the regenerative power. The residual growth theory, which assumes that regeneration is a manifestation of a universal property of all organisms, has to account for the fact that this potentiality is lost in a great many forms.

Two prerequisites must be fulfilled if a successful regeneration is to occur: there must be available the necessary building material in the form of unspecialized cells, capable of growth and differentiation; and the necessary organizing factors must be present which direct the development of these cells. Regeneration may be prevented by the loss of either one or of both. The necessary building material may be lost in the normal course of development, during which embryonic cells undergo a differentiation into highly specialized tissues. This differentiation is undoubtedly irreversible in most instances, and the transformation of all cell materials into an irrevocably differentiated form is

probably one reason for the lack of regeneration in highly organized animals. Some authors maintain that in some instances a differentiated tissue can dedifferentiate and rejuvenate under certain conditions, and thus become available as a source of regeneration material. Furthermore, in a number of invertebrates and lower chordates, certain embryonic cells remain in an undifferentiated embryonic condition and form a reservoir for regeneration and asexual reproduction (*see* below). It is obvious that regeneration is impossible in all those organisms which possess neither reserve cells nor tissues capable of de- and redifferentiation. The organizing or "field" factors for regeneration are discussed below. Their loss, in the course of embryonic development, may be an alternative cause for a lack of regenerative power. Finally, an amputation stump may be potentially capable of regenerating but be prevented from doing so either by a deficiency in one of the many subsidiary agents necessary for regenerative growth, such as hormones or nerve-produced agents, or by a block from a rapidly overgrowing skin or wound scar which prevents the outgrowth of the blastema cells. An appropriate treatment of the stump can call forth a regeneration where it would not occur under ordinary conditions.

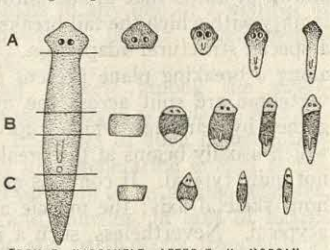
REGENERATION IN DIFFERENT ANIMAL GROUPS

Invertebrates

Protozoa.—Most Protozoa (acellular or one-celled animals) reproduce asexually by longitudinal or transverse fission, or by other modes of division. Fission requires a reorganization and new formation of structures in the daughter individuals, and this process can be considered as a physiological regeneration. The power to rebuild structures is therefore inherent in all protozoans, and it is not surprising to find that most Protozoa can regenerate parts which were lost by accident or removed in an experiment. In all instances, the presence of nuclear material is a necessary prerequisite for successful regeneration. In ciliates, which possess a macro- and a micronucleus, the former is essential; the latter is not. In forms such as *Stentor,* in which the macro-nucleus is represented by a beadlike chain, small segments of the chain are sufficient to enable a fragment to regenerate. In *Amoeba,* which has no highly specialized organelles, a non-nucleate fragment can grow and survive up to 30 days, but it cannot divide. The most highly differentiated Protozoa, the ciliates, have been the subject of extensive studies on regeneration; *Paramecium* and *Stentor* are the favourite materials. Their regenerative power is excellent. Fragments as small as $\frac{1}{64}$ of an individual can form a complete new organism. The new organelles are formed either by remodeling of the remnants of the old ones or by breakdown of the latter and rebuilding of entirely new structures. In parasitic Protozoa the regeneration capacity seems to be poor or entirely missing.

Sponges.—The regeneration of amputated parts in Porifera, or sponges, does not seem to be very extensive. However, a series of interesting experiments revealed a remarkable capacity of the sponge cells to reorganize themselves into a whole organism, following a complete breakup of their organization. Sponges were strained through bolting silk and thus completely dissociated. Following this treatment, small cell groups reunited into larger aggregates which reorganized themselves and eventually formed a typical sponge.

Coelenterates.—These occur in the forms of polyps and medusae (jellyfish). The well-known fresh-water form *Hydra* takes its name from the mythological nine-headed monster which was believed to regenerate two heads in the place of each amputated head. The regenerative power of *Hydra* is at least as startling as that of its namesake. It was on this polyp that the Swiss naturalist Abraham Trembley made the first planned regeneration experiments (1744), which aroused a tremendous interest and were soon followed by those of R. A. F. de Réaumur, Lazzaro Spallanzani and others. Small fragments of the body can regenerate a whole individual (*see* fig. 1). One tentacle with a small portion of the mouth region is capable of forming a new individual. The regenerative power of other hydroids differs in different species. *Tubularia* and other marine forms have been widely used for experiments on the physiology of regeneration.

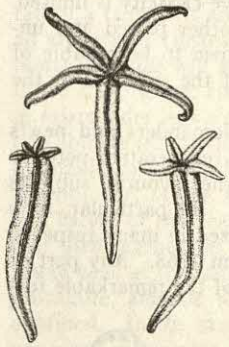


FROM E. KORSCHELT, AFTER T. H. MORGAN

FIG. 2.—REGENERATION IN THE PLANARIAN FLATWORM DUGESIA. THE THREE ROWS SHOW REGENERATION OF (A) ANTERIOR SECTION, (B) MIDSECTION AND (C) POSTERIOR SECTION OF THE ANIMAL AT THE LEFT

The regenerative capacity of the medusae (jellyfish) is much restricted. The Anthozoa (sea anemones and corals) have a considerable regenerative capacity.

Flatworms.—This phylum, Platyhelminthes, includes the planarians, which have an exceedingly high regenerative capacity, and which have therefore been used more than any other form for regeneration experiments. A planarian (*Dugesia*) may be cut in any direction by one or more transverse, longitudinal or oblique sections, and each fragment will regenerate a whole, though smaller, individual (*see* fig. 2). Planarians possess complex structures such as eyespots, brain and pharynx. Any or all of these can be rebuilt from a fragment not containing them. Of three closely related groups of Turbellaria (free-living flatworms), distinguished mainly by differences in the shape of the intestine, only the triclads, or planarians, have a high regenerative power, and even within this group there are great differences with respect to the ability to regenerate.



FROM E. KORSCHELT

FIG. 3.—REGENERATION IN THE STARFISH. ONE ARM REGENERATES A WHOLE STARFISH (CENTRE)

The entirely parasitic flukes (Trematoda) and tapeworms (Cestoda) have not been thoroughly investigated. They seem to lack regenerative power.

Annelids.—Regeneration in the common earthworm is well known. It can regenerate many segments at the posterior part of the body, but regeneration of the anterior part is limited. Up to five segments can be completely restored, but if more are removed, fewer than the normal number are rebuilt; no regeneration takes place if 15 or more anterior segments are amputated. Some relatives of the earthworm can do better. For instance, the fresh-water worm *Criodrilus* regenerates as many as 25 anterior segments. In another fresh-water form, *Nais,* two isolated segments can regenerate a whole worm. One of the remarkable features in these annelid regenerations is the formation of gonads in the regenerated segments, although the stumps which give rise to the regenerates may not contain a trace of gonad material. The regenerative power of the more highly specialized marine polychaetes is, in general, lower than that of the earthworm and its relatives (oligochaetes). It is very low in the leeches (Hirudinea).

Echinoderms.—The arms of starfish (Asteroidea) and brittle stars (Ophiuroidea) can regenerate a whole individual in some instances, even if the amputated arm contains no trace of the central disc. Occasionally, there may be found on the seashore an odd-looking starfish with one or two normal-sized and several very short arms (*see* fig. 3); the latter are in the process of regeneration. Sea urchins can repair damage in the skeleton and restore tube feet and spines. Sea urchin and starfish larvae (plutei) have little regenerative power.

Mollusks.—Parts of the shells of snails (Gastropoda) and valves of clams and relatives (Lamellibranchia) can be replaced. Damage can be repaired at the margin, at which the shell is formed, and also in central parts. The mantle and the foot likewise can regenerate. Some snails have highly complex eyes at the tips of tentacles. The amputation of a tentacle at its base results in its regeneration, including the eye. However, the entire head of a snail cannot be regenerated. Squid, octopus and cuttlefish (Cephalopoda) can regenerate amputated arms.

Arthropods.—The body of an arthropod has many appendages such as legs, wings, antennae, stalked eyes, mandibles and tail.

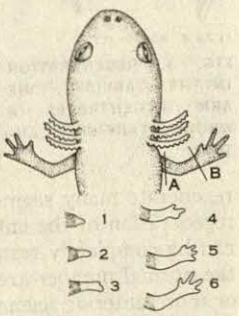
These are all readily exposed to accidental damage, and most of them can be regenerated when lost. This holds particularly for the best-known and most thoroughly investigated groups, the crustaceans (crayfish, crab, lobster, etc.) and the insects. All arthropods molt periodically; that is, they shed the chitinous exoskeleton. Its replacement may be considered a type of physiological regeneration. The regenerative power of insects is high during larval and pupal stages but greatly reduced in the adult. The regeneration of structures such as wings or legs of adult insects is either limited and incomplete or entirely impossible. On the other hand, crustaceans continue to molt throughout adult stages, and they are capable of regenerating complex organs such as legs or eyes.

Sea Squirts.—High regenerative power is found in the sedentary ascidians. A small part of the body can regenerate a whole individual.

Vertebrates

Fishes.—In the bony fishes the regenerative capacity is limited. They can regenerate the tail fins and the other paired and unpaired fins. A few other structures are known to be capable of regeneration, such as the gill cover, parts of the gills and of the lower jaw.

Amphibians.—The tailed Amphibia, salamanders and newts (Caudata), have by far the most extensive regenerative potency of all vertebrates and have therefore been the favourite subjects for experiments on vertebrate regeneration. In particular, limb regeneration of salamanders has been analyzed in many respects, ever since it was discovered by Spallanzani in 1768. Any part of a foot or hindlimb can be regenerated; one of the remarkable features is the precision with which the missing part is restored. If the foot is amputated (fig. 4[B]), only this part is replaced; if the leg is removed at its base (fig. 4[A]), it will be replaced in its entirety. Other organs can regenerate equally well, among them the tail, parts of the snout and eyes and parts of inner organs such as lungs and gonads. The regenerative capacity of salamander larvae and of young specimens exceeds even that of full-sized specimens.



(TOP) FROM V. HAMBURGER, "MANUAL OF EXPERIMENTAL EMBRYOLOGY"; REPRODUCED BY PERMISSION OF THE UNIVERSITY OF CHICAGO PRESS

FIG. 4.—ARM REGENERATION IN A SALAMANDER. 1–6 ARE REGENERATION STAGES. FOLLOWING AMPUTATION AT A; BLASTEMA AT 1 AND 2. (SEE TEXT)

In the tailless Amphibia, frogs and toads (Salientia), the regenerative capacity is limited to larval stages. The tadpoles can readily regenerate a tail which is clipped at the tip or even near the base. The hindleg regeneration proceeds rapidly and efficiently in young tadpoles, but this capacity diminishes when the larva approaches metamorphosis. Adult frogs do not regenerate limbs, contrary to a common belief. Usually the stumps heal without regenerating. If the arm of an adult frog is amputated and the wound surface is bathed repeatedly in a saturated sodium chloride solution, the stump will proceed to form a regenerate. However, the regenerated arm is never complete and normal. It is assumed that in untreated adult frogs the thick skin closes up rapidly over the wound surface and suppresses regeneration.

Reptiles.—Vertebrates higher than Amphibia have greatly reduced regenerative potentialities. The tail of a lizard is the only highly specialized structure in reptilians which can regenerate. The animal makes occasional use of this capacity: when captured by its tail, it shakes the tail off and leaves it behind. Lizards with regenerated tails are occasionally encountered in the field. However, tail regenerates are never complete; their inner structures are atypical. Amputated limbs of lizards do not regenerate.

Birds.—The regeneration of fragments of beaks has been reported in several birds. The periodic renewal of the plumage after each molt is a type of physiological regeneration, and the growth of a feather from a feather rudiment resembles other regenerative processes.

Mammals.—These present numerous instances of tissue regeneration, but very little, if any, evidence for the regeneration of complex structures. The change of hair, of teeth and of red blood cells and the regeneration of antlers in deer illustrate physiological regeneration. Reparative regeneration, following an amputation, is limited to tissues, such as bone, muscle, liver, skin and peripheral nerves. Whole organs cannot be regenerated.

General Concepts

Regenerative Ability.—What general concepts can be derived from this survey? In the first place, it brings into proper relief a point which has been emphasized by students of regeneration since the early days, that there is a correlation between regeneration potentiality and level of organization; *i.e.*, lower organisms have a high regenerative power, and this power decreases with increase in complexity. Mammals, including man, pay for their high organization with an almost complete loss of regenerative capacity. The relation between regenerative power and level of organization, however, holds only in a general way and breaks down in numerous special instances. For example, some planarian species have an exceptionally high regenerative power, but closely related species have none. The same holds for Annelida. The regenerative ability of the fishes is lower than that of the more highly organized tailed amphibians. The regeneration of the crystalline lens of the eye of salamanders is perfect in one genus and absent in another. These examples could be multiplied easily. They show that factors other than the general level of organization of the animal often play a decisive role.

It has also been asserted that since regeneration is a developmental process, embryos, larvae and young animals, in general, should be more readily capable of regeneration than adult stages of the same animal. This expectation is fulfilled in many instances, but again it is not a rigid rule. It is true that salamander larvae regenerate limbs and tails more rapidly and more perfectly than adults do, and lens regeneration in some salamander species is limited to larvae; frog tadpoles can regenerate a hindlimb, but an adult frog cannot. On the other hand, sea urchin and starfish larvae do not regenerate, while the adults do. The same holds for annelids and for tunicates. Again, factors other than age determine the limitation of regenerative power in these forms. Finally, one would expect that external organs and appendages which are readily exposed to injury and loss would show a higher regenerative capacity than inner organs. This, again, holds in a general way. However, several examples have been mentioned of the regeneration of inner organs which are rarely subject to injury during the normal course of life.

Self-Amputation.—A number of animals, when attacked and caught by a leg or tail, save their lives by casting off this appendage. The organ which is sacrificed can usually be restored by regeneration. This act of self-amputation is called autotomy. Instances of autotomy are found in a number of different animal groups, such as coelenterates, mollusks, echinoderms, annelids, arthropods and others, although this means of escape is used by only a few representatives of these phyla.

The only case of autotomy in vertebrates, and perhaps the best known of all, is that of the autotomy of the tail in lizards. The facility with which the tail breaks off is astounding. This is due to a special structural adaptation. When grasped, the tail separates along a breaking plane present at the base of the tail. Several vertebrae are split across the middle. The halves are held together by cartilage which ruptures readily. The regeneration, which usually begins at the breaking plane, produces a tail that is not quite typical. It contains no vertebrae but merely a cartilaginous skeletal axis; the muscle and nerve distribution is likewise atypical. Nevertheless, such a regenerated tail can regenerate a second time.

Many crabs, insects and spiders have a similar device to facilitate autotomy, namely, a preformed breaking plane at the base of legs or antennae. The chitinous exoskeleton is soft and thin at certain levels, and the muscle arrangement expedites self-amputation. It is not always the same segment of the leg at which such a breaking plane is prepared, but the mechanism is apparently sim-

ilar in all species. In the walking stick, or stick insect, all three pairs of legs are adapted for autotomy. Quite frequently, special care is taken to avoid an excessive loss of blood: the skin contracts over the wound and closes it off. A few other instances of autotomy may be mentioned: some sea anemones release a tentacle when it is strongly stimulated; starfishes cast off an arm voluntarily, and some annelids can autotomize the hindmost body segments and regenerate them subsequently.

One of the most startling instances of autotomy is the self-evisceration in sea cucumbers, which, when strongly stimulated, cast off their anterior ends, including tentacles, mouth parts and the water-vascular system, and at the same time discard through the anus the intestine and attached structures, such as gonads. The discarding of the inner organs is accomplished by strong muscle contraction. The nearly empty hull composed of skin and muscles is capable of regenerating the autotomized organs. *Thione* can accomplish this feat within a month.

There is only one step from spontaneous autotomy to spontaneous fission for the purpose of asexual reproduction. For instance, certain starfishes and certain sea cucumbers break apart at more or less regular time intervals and the fragments regenerate a whole individual. Likewise, in certain annelids and flatworms posterior parts of the body are constricted off and the fragments regenerate into new individuals. This performance has been established as a regular mode of reproduction. The close affinity of regeneration and reproduction in lower animals is thus again affirmed.

FIG. 5.—REGENERATION OF A DOUBLE HEAD IN A PLANARIAN (SEE TEXT). REGENERATED TISSUE IS UNSTIPPLED

Atypical Regeneration.—A regenerate is ordinarily a replica of the original structure, but a number of cases are known in which regeneration is atypical in that either more or less than was lost is regenerated. Occasionally, the regenerate represents an organ entirely different from the one it replaces. All forms of atypical regeneration are called heteromorphosis. The last-mentioned category of heteromorphic regenerations is called homeosis.

Incomplete Regeneration.—This type of heteromorphosis is common both in naturally occurring and in experimentally induced regeneration. Regenerated tails of lizards invariably show certain structural deficiencies, such as the absence of normal vertebrae. Regenerated salamander limbs frequently have a reduced number of digits or even greater deficiencies. Those of arthropods may have a reduced number of segments. Several species of annelids can regenerate only a limited number of head segments. If more are amputated, the total segment number of the worm after completed regeneration will be subnormal. Planarians occasionally regenerate a head with two fused eyes, or only one eye, or eyeless heads, instead of the normal head with two separate eyes.

Such atypical head regenerates can be produced experimentally by exposing the regenerating animals to any one of a number of chemical agents which are known to impair developmental processes in a general, nonspecific way.

Superregeneration.—Of greatest interest among the superregenerations are those in which a single organ is replaced by a duplicated or multiple formation. Instances of such monstrosities have been observed in practically all regenerating animal forms, as, for instance, in hydranths of *Hydra* and of its marine relatives, in heads and tails of planarians and annelids, in tails of lizards and limbs or digits of amphibians and particularly frequently in appendages of arthropods. Double claws of crabs or lobsters, double legs and antennae of beetles and of other insects have been described. Starfishes with bifurcated arms and sea cucumbers with duplicated body parts also have been observed. Triplicate appendages are commonest in arthropods and occasionally are found in other forms. They originate probably in most instances in the following way: a leg, claw or antenna ruptures at a joint without breaking off completely. As a result, two wound surfaces are exposed, each of which begins to regenerate the distal parts. The two new formations, together with the persisting original structure, form the triple monstrosity. It was found that such triplicate structures follow a definite rule of symmetry relations (Bateson's rule): two adjacent components, namely, the middle one and one of the marginal components, are mirror images of each other, whereas the two marginal parts have the same symmetry pattern.

It is often difficult or impossible to decide whether double or triple monstrosities found in nature have been brought about by regeneration or whether the duplication occurred in early embryonic development. Therefore, experimental methods were devised that make it possible to study the origin of duplications by regeneration under controlled conditions. An expedient way of accomplishing this is to create a wound surface which will produce two separate blastemas instead of one. For instance, if the tail of a tadpole is amputated by two oblique cuts, in the form of an arrowhead (instead of by one transverse cut), then two blastemas and tails will grow out, each with its main axis perpendicular to the oblique, cut surface (Barfurth's rule). Multiple digits in salamander legs were produced in the same fashion, by making two oblique transections. Two-headed planarians can be obtained by making a longitudinal fission in the median plane through the anterior part of the animal, and a subsequent amputation of the two halves of the head (fig. 5[A]). Each separate anterior body half then regenerates the missing lateral parts and, in addition, a whole head at the anterior surface (fig. 5[B]). By repeating this procedure, animals with multiple heads (up to ten) have been obtained. In the same way, planarians with double tails can be produced experimentally.

Homeosis.—This category of atypical regenerations includes all those instances in which the regenerate represents a structure different in type from the original. Homeosis occurs mainly in arthropods. It is a characteristic of this phylum that most of the numerous body segments bear appendages which are of different types in different body regions (*e.g.*, antennae, mandibles, claws, thoracic legs, abdominal appendages). In homeosis, the appendage of one type substitutes for another type. A few examples may serve as illustrations; in crustaceans (crayfish, lobster, crab), a thoracic leg with claws was regenerated in place of a maxilliped; in other cases an abdominal leg was found in place of a thoracic leg. A leg may be regenerated in place of an antenna or of a mandible, and vice versa. An anterior wing of a butterfly or moth may replace a posterior wing. Of particular interest is the regeneration of an antenna in place of a stalked eye, which was observed in marine decapod crustaceans of the genus *Palinurus*, *Palaemon* and in others (fig. 6). Curt Herbst discovered that if the optic ganglion, which is located at the base of the eyestalk, is removed along with the eye, an antenna grows out, but if the optic ganglion is left intact and the eye alone is amputated, a normal eyestalk and eye regenerate. The ganglion, then, determines the quality of the regenerate.

REGENERATION PROCESS

Origin of Regeneration Material

Blastema Formation.—Regeneration, as noted above, can be performed by reorganization of the old piece (morphallaxis) or by outgrowth of new tissue at the cut surface (epimorphosis). Only the latter mode of regeneration is discussed in the following. In limb and tail regeneration of salamanders, in head and tail regeneration of planarians and in many similar instances, a regeneration bud or blastema is formed at the amputation sur-

face. The blastema is at first a slight elevation which grows to a cone-shaped structure and then begins to differentiate into tissues or organs. The blastema is an accumulation of cells of embryonic type, whose origin has been the topic of numerous investigations. The material that builds up the regenerate may be derived from three different sources. In several invertebrate phyla, including coelenterates, annelids and flatworms, a special type of undifferentiated cells, the so-called reserve cells or neoblasts, are stored in different parts of the body. When the need for regeneration arises they are mobilized and migrate to the site of injury. Tissue outgrowth is a second source. The differentiated tissues at the cut surface (for instance, skin or muscle) may simply grow out and each form tissue of its own kind. Finally, the blastema cells may be derived from formerly differentiated tissues of the amputation stump which have dedifferentiated and returned to an embryonic-type condition. It is conceivable that when the blastema proceeds to develop, such cells may differentiate into a type of tissue different from the one from which they were derived. For example, in salamander limb regeneration, a former muscle cell may become a bone cell, or vice versa. This transformation is referred to as metaplasia (*see* below).

Tissue Outgrowth.—This mode of regeneration is characteristic of tissue repair such as bone regeneration following a fracture, restitution of a muscle injury or liver regeneration. Peripheral nerves regenerate in this fashion, by outgrowth from the cut end. In amphibian limb regeneration, apparently only nerves and skin regenerate in this way. The skeletal elements of the regenerate do not originate from old skeletal tissue at the cut surface. This was demonstrated by an experiment in which the upper arm bone (humerus) was carefully removed and the limb then amputated across the upper arm. The regenerated forearm and digits contained all typical skeletal elements, although no bone tissue was present at the amputation surface.

Reserve Cells (Neoblasts).—A glance at some of the extensive regenerations in lower animals shows that in these cases tissue outgrowth cannot be the primary source of the new formations. For example, a narrow piece from the middle of a planarian can regenerate a new individual, with such organs as brain, eyes, pharynx and reproductive organs, no trace of which was present in the original piece. In flatworms, annelids, coelenterates and tunicates the reserve cells or neoblasts are the major source of the building material for new organs. These cells have been set aside in the embryo for this purpose, and have never undergone any specialized differentiation. In the common coelenterate *Hydra*, which is famous for its regenerative capacity, a type of connective tissue or mesenchyme cell, the so-called interstitial cell, is found scattered throughout the body; these cells migrate to a cut surface and form the chief or even exclusive source of the blastema. In some annelids the neoblasts can be identified as particularly large cells, stored in different parts of the body. However, it seems that tissue outgrowth and metaplasia also contribute to regeneration in annelids, and there is a great deal of variation in details in this group.

Different species of flatworms vary greatly in their capacity for regeneration, and a correlation seems to exist between the degree of regenerative power and the quantity of reserve cells present in the body. The role of these reserve cells in planarian regeneration was firmly established by the use of a modern tool, irradiation. It was found that reserve cells are more sensitive than ordinary body cells to X-rays and other radiation. If the whole animal is exposed to a mild dosage, the neoblasts can be destroyed without destroying the animal, which survives for at least several weeks; these individuals have no capacity for regeneration. A modification of this experiment gave evidence that reserve cells can migrate over long distances to reach the amputation surface. If the anterior part of a flatworm is irradiated and the posterior part shielded, and then the head removed by a transverse cut within the irradiated region, head regeneration occurs with a considerable delay because the reserve cells in the intact posterior region have to migrate across the irradiated band to reach the amputation surface. The wider the band, the longer the delay, but eventually a head is regenerated.

Metaplasia.—The question of whether metaplasia, as defined above, exists is of great theoretical interest: it goes to the heart of the problem of cellular differentiation. Is the process of differentiation of an embryonic cell into a highly specialized cell, such as a muscle or bone cell, reversible? Can a full-fledged muscle cell revert to an embryonic state and then, under certain conditions, differentiate in a new direction and become a bone cell? The origin of the limb-regeneration blastema in salamanders has always been in the centre of this discussion, without, however, yielding crucial evidence one way or the other. First, the question had to be settled whether the blastema cells come from the amputation stump or from more distant parts of the body, or perhaps even from formed elements of the blood. Irradiation experiments gave the answer: if part of a salamander limb is irradiated and the rest of the body shielded, and an amputation is then performed in the irradiated region, regeneration fails to occur; conversely, irradiation of the whole animal, except for the limb, does not interfere with limb regeneration. Contrary to what happens in planarians, then, the blastema cells do not come from distant parts but derive from the cells near the amputation surface.

Microscopic study of the events following the amputation of a limb reveals that a dedifferentiation of differentiated muscle and cartilage or bone actually occurs near the cut surface during the few days preceding the formation of the blastema. The multinuclear muscle fibres break up into fragments forming small cells with single nuclei, which have the appearance of embryonic cells or fibroblasts. There seems to be agreement that these cells, together with similar cells of skeletal origin and with ordinary fibroblasts, contribute materially to the blastema. If by metaplasia is meant merely the loss of highly specialized structure and the transformation into a fibroblastlike embryonic-looking cell, then this is a case in point. But this is not metaplasia in the strictest sense. The crucial question is still open: Have these cells actually lost all their biochemical and metabolic specifications? Have they reverted to a true embryonic pluripotential state which would enable them to differentiate into a cell type different from the one they represented before? A definitive answer to this question awaits new techniques.

There is, however, one clear case of true metaplasia. This is the regeneration of the crystalline lens of the salamander eye, often referred to as Wolffian lens regeneration in recognition of one of the co-discoverers and most active students of this very remarkable phenomenon. If the lens is carefully removed with fine instruments, it is replaced by a new lens that originates at the upper margin of the iris; the latter is the pigmented part of the eye, enclosing the pupil. The first change, following lens extirpation, is the disappearance of the pigment in the upper iris; that is, a process of dedifferentiation. Next, the two tissue layers that comprise the iris separate and expand at the rim where they are continuous, and form a small vesicle. This vesicle grows downward to assume the normal position of a lens; eventually it becomes detached from the iris and differentiates into a typical lens. Here may be observed directly the transformation of pigmented iris cells into lens cells. Another case of true metaplasia, the regeneration of brain tissue from epidermis in annelids, is well documented.

Regulation

Initial Stimulus.—The regeneration process is ordinarily initiated by the injury that accompanies the loss of a part. The trauma seems to play an activating role similar to that of fertilization in the egg. The physiological and metabolic equilibrium at the wound surface is undoubtedly disturbed, and it is likely that the injured tissues produce a chemical agent or agents that set the process in motion. However, the actual loss of a part is not a necessary prerequisite for regeneration. An injury such as an incision in the stem of a coelenterate or in the body of a planarian is sufficient to initiate a new growth process. If ultraviolet irradiation is applied to the elbow region of a salamander limb, a local injury ensues, and an accessory, well-formed forearm with digits may grow out at this place. Duplications of limbs and other organs encountered occasionally in amphibians, arthropods

and other groups, may have originated this way, by local injury.

In some instances not even an injury is necessary for activation of the regeneration process. The above-mentioned lens regeneration in the salamander eye is initiated simply by removal of the old lens, which can be done without injury to the upper iris, from which the regenerating lens is derived. What is the stimulus in this instance? Experiment has shown that the lens produces a chemical agent that holds the upper iris in check. If this inhibitor is removed, along with the lens, the regeneration process is set in motion. The coelenterate *Tubularia,* a marine relative of the common *Hydra,* which has been widely used for regeneration experiments, consists of stolon, stem and hydranth, the latter containing the mouth opening surrounded by two rows of tentacles (fig. 8). The stem is sheathed in a transparent coat, the perisarc. If a small area of the stem tissue is exposed to sea water by cutting a hole in the perisarc, a bud grows out at that place and forms eventually a new hydranth. In this instance, the local increase in oxygen tension serves as the activating stimulus. This experiment again illustrates the close relationship between regeneration and asexual reproduction by budding.

Regeneration Fields in Amphibians.—Once a blastema is formed, it is possible to inquire into the organizing factors that so direct the further development of the blastema that exactly the missing parts are replaced. The problems faced here are similar to those the embryologist encounters when he tries to analyze the factors that determine the origin of an embryonic organ primordium (*see* EMBRYOLOGY AND DEVELOPMENT, ANIMAL: *Experimental Embryology*). The regeneration blastema can be considered as equivalent to an organ primordium; the same types of organizing and determining factors probably are in operation in both, and the same kinds of experimental methods, such as extirpation and transplantation, are applied for their analysis. It should be stated that analysis of the regeneration process is much less advanced than that of embryonic processes.

The concept of regeneration fields has been found useful for an understanding of regeneration phenomena; the field concept also has been applied to embryonic development. The capacity for regeneration of an organ such as limb, tail or snout in salamanders is limited to a well-circumscribed area. For instance, limb regeneration after amputation can be obtained at any level down to the base, but if a still larger area, including the limb girdle, is removed, no regeneration occurs. By this type of extirpation experiment, regeneration fields for different organs have been demarcated. The fields are the units of regeneration; therefore, it is not quite correct to say that the salamander regenerates a limb; rather, the limb regeneration field restores its wholeness when it has been impaired. The field concept conveys another notion: the organizing factors for regeneration are distributed over the whole field in such a fashion that if the field district is injured at two separate points, two regenerates of the same type can be formed. In this way, duplicate limbs or tails can originate by experiment or by accidental injury. An example is an experiment mentioned above in which local irradiation at the elbow of a salamander called forth the formation of an extra limb. If a field can give rise to more than one organ, then part of a field should be able to produce a whole organ. This expectation is fulfilled in the following experiment: if the salamander hand is amputated and the forearm split lengthwise, each half of the cross section can regenerate a whole hand with four digits. The regeneration field shares this remarkable regulative property with the embryonic fields.

Determination.—Very young limb or tail blastemas apparently resemble early embryonic structures in that they are not yet irreversibly determined but show a certain plasticity. If a few-days-old blastema of a salamander forelimb is transplanted onto the stump of an amputated hindlimb, the regenerate is a hindlimb. However, if the blastema is a week old, or older, it forms a forelimb in a foreign position; that is, its fate has been determined in the meantime. Obviously, the blastema acquires gradually its specific characteristics. It must get its "instructions" from the underlying stump tissue, but the determinative mechanisms are unknown.

Organizers and Induction.—The discoveries of inductors and organizers were landmarks in experimental embryology. Transplantation experiments showed that certain embryonic areas, called inductors, produce chemical agents that stimulate the formation of an organ, such as inner ear, nose, lens, in an adjacent embryonic area. The organizer, discovered by H. Spemann in early amphibian embryos, is a complex inductor that, when transplanted to another embryo, induces in the latter not merely a single organ but a more or less complete secondary embryo. Similar phenomena were discovered in the regeneration of lower forms. If a small piece from the mouth region of a coelenterate polyp (fig. 8) is transplanted into the stem of another individual, a secondary individual grows out, composed largely of host material; the transplant contributes the organizing factors but little material. Similarly, if a piece of the head of a planarian is transplanted to the middle of the body of another planarian, a secondary individual is induced. If individuals of different colour are used in this experiment, it is possible to establish clearly the share of the graft and of the host in the new formation, and it can be seen that the graft forms only a small part of the outgrowth. Obviously, it is important to distinguish between organizing factors and building material.

Organ induction also has been demonstrated. In certain species of planarians, the brain produces a diffusible substance that induces eye regeneration. In the above-mentioned case of lens regeneration in the salamander eye from the upper iris, it is not enough to remove the lens-produced inhibitor; in addition an inductive substance, produced by the retina of the eye, must be present.

Role of the Nervous System.—The presence of nerves at the cut surface has long been recognized as a necessary prerequisite for amphibian limb regeneration. No regeneration takes place if simultaneously with limb amputation all limb nerves are transected in the region of the limb girdle. However, the nerves themselves can regenerate, and as soon as the regenerating nerves reach the amputation level a belated blastema formation begins. Limb regeneration can be prevented permanently by repeated nerve transections. If this is done in larval salamanders, not only is there no regeneration, but the amputation stump begins to regress and is eventually completely resorbed. The nerves apparently produce a trophic (nutritive) agent of unknown chemical nature that promotes the blastema formation. Once the blastema has reached a certain size, it becomes independent of the nerve influence. This trophic factor should be counted among the general, nonspecific metabolic conditions for regeneration, and not in the category of specific organizing factors, because the nerves do not determine the specific quality of the regenerate; they do not decide whether it is to be a forelimb or a hindlimb. The question of whether any special nerve fibre type, such as sensory, motor or sympathetic, is responsible for the production of this trophic agent was a matter of controversy for a long time, the issue being finally settled by M. Singer, who found that the requirement for nerves is quantitative, not qualitative; a certain minimum number must be present at the amputation surface, but the source from which they are derived is immaterial.

The nervous system also plays a role in the regeneration of certain invertebrates. For instance, head regeneration of the earthworm seems to be dependent on the presence of the ventral nerve cord at the amputation surface. Eye regeneration in some marine decapod crustaceans presents a particularly interesting case.

A normal eye regenerates if the eye and eyestalk are removed but the optic ganglion at the base of the stalk is left intact; if the latter is also removed, then an antenna is formed in the place of the eye (fig. 6; homeosis).

In other arthropods antennae and legs can regenerate in the absence of nerves.

Hormones in Regeneration.—Hormones (*q.v.*) play an important role as agents controlling a great variety of body functions. Their influence on growth and development is illustrated by the well-known cretinism, which results from deficiency of the thyroid hormone, and by the control of amphibian metamorphosis

by the thyroid gland. The pituitary body (*see* PITUITARY GLAND) produces a growth hormone; its underproduction results in dwarfism and its overproduction in gigantism. Since regeneration is a special type of growth and development, similar hormonal influences on regeneration would be expected, and this is indeed the case.

The regeneration of limbs in adult newts (tailed amphibians) is inhibited when the entire pituitary is removed. This effect is exerted only on the very first phase of the regeneration process, following amputation, namely the breakdown of tissue (dedifferentiation) near the cut surface. Instead of formation of the blastema, a thick pad of skin grows over the wound and blocks further outgrowth.

Regeneration proceeds in a normal fashion if the regeneration process is allowed to get a start of five or six days before the gland is removed. It is assumed that the hormone is involved in the breakdown of proteins. Thyroid hormone has a similar effect on amphibian limb regeneration, and hormonal effects on regeneration in insects also have been reported.

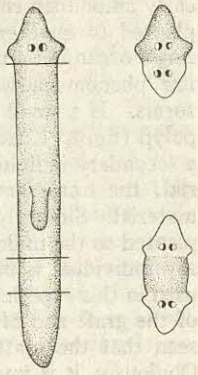

FIG. 7.—POLAR HETEROMORPHOSIS (REVERSAL OF POLARITY) IN A PLANARIAN. AN AMPUTATED HEAD OR A SHORT POSTERIOR BODY PIECE MAY REGENERATE A HEAD WHERE A TAIL WOULD BE EXPECTED. REGENERATED TISSUE IS UNSTIPPLED

Polarity; Gradient Theory.—The familiar distinction between head, trunk and tail, or anterior and posterior end, calls attention to the axial organization, or polarity, of most animals. In the polyps of coelenterates, polarity is expressed in the formation of a tentacle-bearing hydranth with mouth opening at the apical end of the stem and a stolon at the basal end (fig. 8). One of the striking phenomena in the regeneration of lower animals is the retention of polarity even in small fragments.

A slice of a planarian taken from any part of the body regenerates a head at the anterior cut surface and a tail at the posterior cut surface. However, exceptions do occur; reversal of polarity is referred to as polar heteromorphosis (fig. 7).

How can the maintenance of polarity in regenerates be explained? Older theories that postulated specific cell types or specific morphogenetic substances for head or tail formation have been abandoned. The axial gradient theory of C. M. Child offers a more dynamic interpretation. According to this theory, polarity is the manifestation of a gradient of physiological activities along the main axis, the head end representing the highest activity and the tail end the lowest. Each section of the body or stem shares in this axial gradient. The theory assumes further that a head, or hydranth in coelenterates, regenerates at the anterior surface of an isolated piece because this is the region of relatively highest metabolic activity in the fragment; and the tail or stolon forms at the level of relatively lowest activity. In other words, the fate of a regeneration blastema is determined by its relative position in the whole gradient system.

Polar heteromorphoses, which occur predominantly in very short pieces (fig. 7), are explained by assuming that in such pieces the activity at the two surfaces is nearly equal and the differential too small to determine two different types of structures.

The nature of the physiological activity postulated by the theory has never been clearly defined, and efforts to demonstrate single gradient systems of oxygen consumption or of other general metabolic activities, consistent over a wide range of eggs, embryos and lower animals, have failed. However, there are some indirect methods that give indications of rather widespread gradients, for instance in the susceptibility of lower animals, eggs and embryos to toxic agents. In this context, gradients of regeneration capacity are of special interest. In the stem of the coelenterate *Tubularia* the rate of regeneration, measured by the amount of tissue regenerated per hour, decreases gradually from the apical to the basal regions; this is attributed to the gradient concentration of a catalyst. Likewise, if a planarian is cut in six or eight transverse pieces of equal size, the quality of head regeneration is highest in the anteriormost piece and declines from there in a graded fashion.

The concept of physiological dominance is an integral part of the axial gradient theory. It is postulated that the region of highest physiological activity not only forms a head or a hydranth but at the same time suppresses head or hydranth formation at any other part of the regenerating piece. It sets itself up as a "dominant region" and thus guarantees the unity in the regenerating system. One experiment, selected from many others, may illustrate dominance. As illustrated in fig. 8, a piece of the stem of the coelenterate *Tubularia* would normally regenerate a hydranth at the apical end, at surface 1, and a stolon at surface 2. If regeneration at the apical end is prevented by a ligature, then the basal end regenerates a hydranth. In terms of the theory, the ligature has eliminated all influences of the apical region; thus, the basal end has been released from the inhibitory effect of the original dominant region and set itself up as a new dominant region. A polar heteromorphosis has thereby been produced.

Nerve Regeneration.—The great practical importance of nerve regeneration following nerve injury in man justifies a brief special consideration of this process. Only peripheral nerves can regenerate; the nerve cells, or neurons, that make up the tissue of the brain and spinal cord, and the ganglia, cannot be replaced once they are destroyed. The peripheral nerves are actually bundles of nerve fibres embedded in connective tissue. Each fibre is a delicate protoplasmic thread spun out in early development by one of the nerve cells in the central nervous system or ganglion. The fibre remains part of its cell of origin and depends on its cell body for nutriment throughout life. This fact is important for an understanding of nerve fibre regeneration. When a nerve is transected, regeneration starts from the so-called proximal stump of the fibre (that is, the part that remained connected with its cell body), whereas the disconnected, distal or peripheral stump dies off. The fibres at the proximal stump begin to sprout new threads that penetrate the gap between the two cut ends.

How do these fine processes bridge this gap? How do they find their way to the peripheral organs they are supposed to reinnervate? They obtain substantial aid from a special type of companion cells, the so-called Schwann cells. These very versatile small cells serve several important functions. They are lined up all along the nerve fibre, forming a continuous, very delicate coat around it. During development, they produce an insulating coat around the fibre, the so-called myelin sheath, which gives the nerve its white, glistening appearance. In nerve regeneration, they play a major role in reconstructing the peripheral pathway for the regenerating fibres. The peripheral parts of the nerve fibres themselves that were severed from their cell bodies break down and disappear; not so the Schwann cells that surround them. These become very active. They multiply and form long dense strands, or cords, in the peripheral nerve stump.

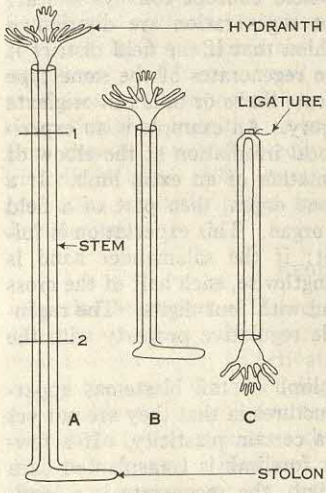

FIG. 8.—EXPERIMENTAL REVERSAL OF POLARITY IN THE MARINE POLYP TUBULARIA, ILLUSTRATING PHYSIOLOGICAL DOMINANCE. (A) PIECE 1–2 REGENERATES NORMALLY (B) A HYDRANTH AT 1 AND A STOLON AT 2. (C) IF A LIGATURE IS MADE AT 1, A HYDRANTH REGENERATES AT 2

These cords are then invaded by the newly regenerating fibres from the proximal stump and serve the outgrowing fibres as a substrate and a guide, from the cut end all the way to their destination at the periphery.

The greatest hazard for the regenerating nerve fibres is the crossing of the gap between the two cut ends of the nerve. In this they are also aided by the Schwann cells; the latter, together with fibroblasts, form between the two cut ends a bridge of parallel strands which is then

used as a track by the outgrowing fibres. In this phase of nerve regeneration, the surgeon can lend a helping hand by facilitating the crossing of the gap. Particularly if the gap is wide, the two ends may be connected with sutures, or fitted together with a sleeve made of a piece of artery or other material. Growth of the regenerating nerve fibre proceeds at the rate of several millimetres per day. In man, functional recovery takes several months, the time depending, of course, on the distance between the cut end and the peripheral end organ.

(V. H.)

REGENSBURG (RATISBON), a city and episcopal see of West Germany in the *Land* (state) of Bavaria, Federal Republic of Germany. Pop. (1961) 125,047. It lies 61½ mi. (99 km.) SE of Nürnberg by road, on the right bank of the Danube at its most northerly bend, where it is joined by the Regen. From Roman times it has been a trading centre and is now a road and rail junction and river port, the Danube being navigable there for most of the year for large barges. Goethe said of Regensburg: "Such a site was bound to attract a city." Its medieval buildings have been almost entirely preserved, the patricians' houses with their imposing towers (12th–14th centuries) being unique in Germany. The Steinerne Brücke ("stone bridge"; 1135–46) across the Danube, linking the suburb of Stadtamhof, was a medieval constructional wonder.

The Cathedral of St. Peter (1275–1530) is the most important Gothic church in Bavaria, with a beautifully proportioned interior and fine stained-glass windows (14th century). The cathedral choir (Regensburger Domspatzen) is well known. In the adjoining cloisters are two Romanesque chapels. St. Emmeram's Church is a Romanesque basilica, the interior having been remodeled in the Baroque style. The buildings of the Benedictine abbey of St. Emmeram (founded 7th century) have been since 1812 the palace of the princes of Thurn and Taxis. In the Alter Kornmarkt (Old Grain Market) are the remains of the Herzogshof, the residence of the Bavarian dukes (13th century). Nearby is the Alte Kapelle (Old Chapel), rebuilt by Henry II in 1002, with an elaborate Rococo interior. The Schottenkirche St. Jakob, founded by Irish monks, is a Romanesque basilica (12th century), the north portal having unusual Christian and pagan sculptured figures. The Dominikaner Church (13th century) is an early Gothic basilica. The town museum incorporates the Minorite Church (*c.* 1250–1350). The Town Hall (14th–15th centuries with a Baroque extension) contains the Reichssaal (*c.* 1350) with fine tapestries. The Imperial Diet was held in that building during the period from 1663 to 1806.

In the town museum is a Roman tablet commemorating the founding, in A.D. 179, of Castra Regina, a legionary camp and a main Roman stronghold; the north gate (Porta Praetoria) and parts of the walls still survive. Earlier it was a Celtic settlement (Radasbona); and the Romans first camped there in A.D. 77. In 530 Regensburg became the capital of the dukes of Bavaria. St. Boniface made it a bishopric in 739 and shortly afterward it became the capital of the Carolingians. During the 12th–13th centuries Regensburg, an imperial free city from 1245, was the most prosperous city in southern Germany. In the Thirty Years' War it was taken by the Swedes and then by the imperial troops. The French sacked and burned it in 1809 and in the following year it became part of Bavaria. The astronomer Johannes Kepler died in Regensburg in 1630. The painter Albrecht Altdorfer (d. 1538), examples of whose works are in Regensburg, was city architect and a counselor.

The city is an important industrial and commercial centre, leather, electrical, and chemical goods being the chief manufactures, and sausage is a speciality.

See F. Voggenneiter, *Die Stadt Regensburg* (1936).

REGENT, one who rules or governs, especially during the absence, minority or incapacity of the sovereign. William I of England appointed *ad hoc* administrators whenever he left for Normandy, and in the course of the 12th century it became customary for the justiciar to act as regent when the king was abroad. In 1216 the barons chose the earl of Pembroke to be *rector regis et regni* ("guide of king and kingdom") for the boy king, Henry III. By the statute of 28 Henry VIII c. 7, advance provision was made for the selection of a regent upon Henry's death to serve until the new sovereign should attain the age of 18 if a male or 16 if a female. Although it was always subsequently assumed that a regent could be appointed only by or pursuant to an act of parliament, it was not until the Regency Act, 1937, that permanent provision was made for the selection of a regent if the sovereign is under 18 or is found by a commission composed of his or her spouse, the lord chancellor, the speaker of the House of Commons, the lord chief justice and the master of the rolls to be infirm of body or mind.

At the universities of Oxford and Cambridge the term regent was applied to a resident master who presided over disputations in the schools, and Cambridge once called the upper house of the university senate Regent House. In the Scottish universities the term designated a tutor for undergraduates; in France it designated a teacher of elementary arts or sciences in a secondary school. The term was occasionally used in Europe and elsewhere to refer to the governing board of a city, and in some Muslim states for the chief of state. In Java it was the title given to a native chief through whom the Dutch colonial officials governed a residency. In the United States the term is little used except by some educational institutions, especially state universities, for a member of the governing board; *e.g.*, the regents of the University of California.

(J. A. C. G.)

REGER, (JOHANN BAPTIST JOSEPH) MAXIMILIAN, known as MAX (1873–1916), German composer and teacher who developed the neoclassical tradition in German music inherited from Brahms, was born at Brand, Bavaria, on March 19, 1873. He studied at Weiden and in 1888 visited Bayreuth where he heard *Die Meistersinger* and *Parsifal*, but the Wagnerian influence was short-lived. From 1890 to 1893 he studied with the musicologist Hugo Riemann at Sondershausen, and at Wiesbaden where he also taught the piano, organ, and theory. From this period dates his friendship with Busoni, and also with the Leipzig organist K. Straube, who introduced Reger's organ music. He returned to Weiden in 1898. In 1901, in spite of much opposition to his traditional methods, he established himself as a composer, pianist, and teacher in Munich. In 1902 he married Elsa von Bercken (née Bagenski). In 1906, after writing many organ, piano, and chamber works, he produced his first orchestral work, the Sinfonietta, Op. 90. The following year he was appointed professor of composition at the Leipzig Conservatory and musical director at the University of Leipzig. There he wrote many choral and orchestral works, chamber music, and songs. In 1909 he went to London where he took part in performances of his chamber works. In 1911 he was appointed conductor of the court orchestra at Meiningen where he wrote his *Böcklin Suite* and one of his finest works for orchestra, the *Variations and Fugue on a Theme by Mozart*. He spent the last year of his life at Jena and died at Leipzig on May 11, 1916.

In an age of bold harmonic experiments Reger used the conventional musical language which, however, he developed in a personal way. One of the last composers to infuse life into the 19th-century style, he influenced forward-looking composers of the following generation, among them Honegger and Hindemith. His organ pieces, notably his Fantasy and Fugue on the letters of Bach's name, and his songs, some of them dedicated to the memory of Schubert and Wolf, are best known. His orchestral works include the *Suite in the Old Style* and sets of variations on themes of J. A. Hiller and Beethoven. A Reger Society was established in Ger-

many in 1920 and in 1954 a complete edition of his works was begun at Bonn.

See E. Otto, *Max Reger: Sinnbild einer Epoche* (1957).

REGGIO DI CALABRIA, a city of southern Italy and capital of the province of the same name, is on the Strait of Messina, 338 mi. (544 km.) SSE of Naples by road. Pop. (1961) 152,071. It is an archiepiscopal and metropolitan see.

Reggio has been destroyed many times by earthquakes and by Saracen invaders. Repeatedly reconstructed, it has experienced alternately splendour and decadence. It was completely razed in an earthquake on Dec. 28, 1908, and was afterward rebuilt with wide streets and low, reinforced-concrete buildings. The cathedral was rebuilt in Romanesque-Byzantine style. The Museo Nazionale della Magna Grecia, designed by Marcello Piacentini, contains a notable collection including tablets from Locri (*q.v.*) and pictures by Antonello da Messina.

Reggio is linked with Messina, 9½ mi. (15 km.) across the strait, by steamer and train ferry. It is connected by rail northward with Naples and southward with Melito di Porto Salvo. There are air services to Rome and Palermo. Reggio is a tourist resort and seaport, and supplies the perfume and pharmaceutical industries with essences of bergamot and jasmine. Another important export product is dried pungent herbs.

The city of Rhegion (Latin Rhegium) was founded *c.* 720 B.C. by Greek colonists from Chalcis as a daughter city to Zancle (Messina). Under Anaxilas, who also ruled Zancle, it prospered, but in 387 B.C. it was captured by Dionysius I. Later it suffered under the Mamertini (mercenaries from Campania) until it fell to the Romans in 270 B.C. Throughout the Punic Wars the city was faithful to Rome, but remained a Greek city even under the empire and never became a colony. It was taken by Alaric in A.D. 410, by the Saracens in 918, and by the Normans in 1060. It was damaged during World War II.

REGGIO DI CALABRIA PROVINCE comprises the southern part of Italy's "toe." Area 1,229 sq.mi. (3,183 sq.km.). Pop. (1961) 582,409. The east and south of the province are mountainous, with the Aspromonte Range (Montalto, 6,417 ft. [1,950 m.]) near the southern extremity. In the west, where a coastal plain borders the Gulf of Gioia, fishing is carried on. Sheep and goats are raised and citrus fruit, olives, and grapes are grown. Apart from the capital the chief towns are Gioia Tauro, Palmi, and Locri, which all have some industry. (A. LA T.)

REGGIO NELL'EMILIA, capital city of the province of the same name in the region of Emilia-Romagna, north central Italy, is situated near the southern edge of the Po plain on the Crostolo River (a minor affluent of the Po) 25 mi. (40 km.) NW of Bologna on the road and rail route from Rimini to Milan. It is an episcopal see. Pop. (1961) 118,375. The Via Emilia (Roman Via Aemilia) runs through it. The cathedral (9th century) was rebuilt in the 16th century by Bartolomeo and Prospero Spani; opposite is the house where the poet Ludovico Ariosto was born in 1474. There is a modern garden-city suburb. The town is a centre for local farm produce; wine, cheese, meat products, electrical apparatus, cement, and pharmaceutical products are made.

Founded in the 2nd century B.C. by Marcus Aemilius Lepidus as Regium Lepidi, Reggio was ruled from the 15th to 18th century by the Este family and was annexed to Piedmont in 1860.

REGGIO NELL'EMILIA PROVINCE (area, 885 sq.mi. [2,291 sq.km.]; pop. [1961] 371,389) adjoins Mantova (north), Modena (east), Parma (west), and Massa-Carrara and Lucca (south). It extends from the ridge of the Etruscan Apennines, which form its southern half, to the Po River, whose valley forms its northern half. The Secchia and Enza rivers approximately delimit its eastern and western boundaries. Dairy cattle are raised; grapes are grown on the southern hillsides, and wheat on the northern plain. There are several small towns of historical interest. The ruined castle of Canossa (*q.v.*) is 12 mi. (19 km.) SW of Reggio. (M. T. A. N.)

REGICIDE means the killing, or the killer, of a king (*see* KING for ritual regicide). Christian moralists connect the act with tyrannicide, the killing of a tyrant, which some forbid absolutely but which others condone in certain circumstances. Regicide became an issue with the execution of Mary Queen of Scots in 1587, the assassination of Henry III of France in 1589, and the assassination of Henry IV of France in 1610. Whereas Jean Bodin (*q.v.*) had maintained that the kings of France, England, and Spain, having no lawful superiors to judge them, could not lawfully be killed, the Spanish Jesuit Juan de Mariana (*q.v.*), in his *De rege et regis institutione* (1599), advanced some highly democratic arguments for regicide, for which the Society of Jesus was widely attacked, despite its disavowal of Mariana's theses in 1610.

In England the name regicide is given to those responsible for the sentencing and execution of Charles I (1649). At the Restoration (1660) the House of Commons first specified 84 of these "regicides" (including the two disguised executioners, whose identity was unknown). The following provisions were included in the Indemnity Act (August 1660): (1) the 4 most notable "regicides," John Bradshaw, Oliver Cromwell, Henry Ireton, and Thomas Pride, who were all dead, were excepted from indemnity (in January 1661 their bodies, except Pride's, were exhumed and hanged at Tyburn); (2) the estates of 20 other deceased "regicides" were to suffer fine or forfeiture; (3) 26 living "regicides" were totally excepted from indemnity, as were the two executioners and 4 others not numbered among the original 84; (4) 19 more living "regicides" were also excepted, with a saving clause that, if attainted, their execution must be specially authorized by Parliament. Of the remaining "regicides," 7 were debarred from office for life and 4 (of whom one was dead) were pardoned.

The trial was held in October 1660. There were 10 sentences of death executed forthwith, and 19 imprisonments (one man was later freed and two escaped). Of the 18 who had escaped arrest, 3 went to New England, the others to the continent of Europe. Of the latter, 3 were captured in Holland, taken to England, and executed (1662), and one was shot dead at Lausanne (1664).

In later French history the name regicide is given to those members of the Convention who sentenced Louis XVI (*q.v.*) to death. In the session of Jan. 16–17, 1793, there were 361 votes for death outright, 26 for death but with a preliminary debate on the expediency of postponing execution, 46 for a suspended sentence of death (*sursis*), and 288 for alternative penalties. In the final session (Jan. 19–20), there were 380 votes for death against 310 for the suspended sentence.

REGIMENT, in most armies, a body of troops headed by a colonel and organized for tactical control into companies, battalions, or squadrons. French cavalry units were called regiments as early as 1558. The word is derived from the Latin *regimen,* a rule or system of order, and describes the regiment's functions of raising, equipping, and training troops. As a regiment developed individuality, through its name or number, colours, coat of arms, distinctive uniform and insignia, and achievements in battle, it also became a central object of loyalty, pride, and *esprit de corps* of its soldiers.

In early U.S. service, as in European armies up to that time, the usual number of companies in a regiment was ten, forming a single battalion in battle. Early in the 19th century, Napoleon Bonaparte organized the regiments of the French Army into three battalions or squadrons, of which two were in the field and one was in quarters recruiting and training additional troops. Later, Edward Cardwell (afterward Viscount Cardwell) reorganized the British infantry into two-battalion regiments, each having one battalion at home and one stationed overseas. The U.S. Army adopted a three-battalion infantry regimental organization in 1901, and incorporated regiments of this type in the divisions employed in World Wars I and II and the Korean War.

Artillery batteries of the U.S. Army had been formed into regiments as early as 1821, but the organization of artillery units was changed frequently until after World War II, when the battalion organization emerged as standard practice. Similarly, the U.S. cavalry regiments in service in the western territories during the 19th century eventually gave way to separate tank battalions and reconnaissance squadrons. In the British and Commonwealth armies, comparable artillery and armoured units of battalion size are still called regiments.

In 1957 the U.S. Army, during a major reorganization of its

divisions, eliminated the infantry regiment as a tactical organization. (*See* DIVISION, MILITARY.) Concurrently, it inaugurated a Combat Arms Regimental System, in which each infantry, armour, and artillery tactical unit was identified as part of a historic regiment, carrying its name and colours and inheriting its traditions and battle honours. Thus, each regiment consisted of a varying number of separate tactical units distributed among the divisions and other organizations comprising the combat forces of the Army.

(E. SR.)

REGINA, the capital and largest city of the province of Saskatchewan, Can., is located in the south central part of the province, 357 mi. W. of Winnipeg. Founded in 1822 as Pile O' Bones and renamed Regina, it was capital of the Northwest Territories from 1882 to 1905, having been chosen because of its central location on the Canadian Pacific railway, and was selected as capital city when Saskatchewan became a province in 1905.

Regina is a busy distribution centre serving a rich agricultural area. Both major Canadian railway systems serve the city and five main highways converge on it, one of these the Trans-Canada. Regina is on the main Trans-Canada Air line and has regular air service with most other Saskatchewan cities. It has good daily newspaper service, a television station on a national hookup and three radio stations. It obtains abundant natural gas from provincial sources and uses local artesian and Saskatchewan river water for domestic and industrial needs.

Regina experienced rapid physical expansion and economic development after World War II and became an important prairie manufacturing centre. Its industry includes two large oil refineries, one co-operatively owned; extensive assembly plants; a cement plant; a brewery; and various services to the petroleum and agricultural industries. A steel production and fabricating industry was established in the early 1960s.

Regina is the provincial government seat, with its legislative and administration buildings, various government and educational institutions including a provincial university college, several affiliated colleges and the provincial natural-history museum. It is the headquarters for Canada's largest co-operative, the Saskatchewan Wheat Pool, and has been an important centre in the growth of the co-operative movement in Canada. Pop. (1961) 112,141.

(C. S. BR.)

REGIOMONTANUS: *see* MÜLLER, JOHANN (REGIOMONTANUS).

REGIONAL PLANNING, a term used by political scientists, engineers, sociologists, geographers and others to describe the process of considering systematically the functional organization of the natural and human resources of an area of the earth. Regional planning may involve extensive areas that include one or more nations or more limited areas such as drainage basins or metropolitan areas. The objectives may be general or specific. Examples of international regional planning include the European common market and the Colombo plan (*q.v.*), involving whole nations, the St. Lawrence seaway (*q.v.*) and the Nile valley and Amur river schemes, involving parts of two or more nations. In many instances a regional plan involves the creation of a new organization for its particular purpose as, for example, the Tennessee Valley authority, the boundaries of whose area coincide with those of no general political jurisdiction but which in its operation involves the co-operation of several to their mutual advantage.

Regional planning is essentially a process of orderly and systematic anticipation of the future of a region, involving recommendations of the necessary remedial and constructive actions by public and private agencies to achieve the objectives of the plan. In one sense it is as old as society. In modern times, significant contributions to knowledge of planning principles have been made by geographers who are concerned with the nature of man's occupancy of the earth and of its regional similarities and differences; by economists whose concerns include the flows of goods, money and credit to, from, and within regions as well as theories relating to the location of economic activity; by sociologists who are concerned with the regional aspects of the organization of society and of social action; by political scientists whose concern includes the institutional means by which plans are made and effected; by psychologists, philosophers and others concerned with motivation and the setting of social goals; by engineers, architects and others concerned with the physical structures and forms involved in man's utilization of resources; and by specialists in many other fields.

Planning does not set goals or objectives within a society; it rather points out the consequences of alternative decisions relating to the utilization of resources and the organization of society in space and recommends programs of action considered most appropriate and effective in the light of the objectives which the particular society sets for itself.

The Nature of Regions.—Regions are human creations for the purpose of analysis, synthesis and planning. The extent and character of a region will depend upon the purpose or purposes for which it is created and the number of possible regions is infinite. Geographers recognize two types: homogeneous and nodal. Homogeneous regions are areas within which, for the purposes for which the region is being defined, the similarities from place to place are considered to be more significant than the differences. Such similarities may be in a single element, such as climate, soils, population density, drainage characteristics, religion or language. For multipurpose planning or comprehensive planning a combination of elements is employed in defining a region; two or more of these may exhibit coincidences in their variations or may on the other hand show no significant variations from place to place within the region. The second type of region is the nodal region, which is an area of concentration of elements or activities, such as an urban or metropolitan area or the intensively developed core of a more extensive homogeneous region.

A major difficulty in preparing and especially in effecting a regional plan is that most appropriate real units very rarely coincide with a governmental jurisdiction. Metropolitan areas such as New York, Chicago, London, Tokyo and Paris involve many municipalities and other units of local government; river basins seldom are included entirely within individual states or provinces and many of them such as the Rhine, Rio Grande, Columbia and Congo, are international. The co-ordination of capital improvement programs of a multiplicity of units of government presents a challenge to the planner. In some instances the problem can be solved by the creation of new units of government, such as the metropolitan municipality of Toronto and the various types of special-function authorities such as the Port of New York authority, the metropolitan sanitary district of Greater Chicago and the Tennessee Valley authority.

The Process of Regional Planning.—Whether the planning is for a homogeneous or a nodal region, whether comprehensive or special-purpose, and whether undertaken by a regular governmental unit, a special public agency or a private organization, it involves several steps: (1) inventory and survey of the resources or other elements relative to their character, quantity, quality, availability and distribution within and without the area; (2) analysis of the relationships among the natural and human resources of the region and of their significance; (3) making of the plan, including proposals for maximizing the effectiveness of utilization of the resources in terms of the plan objectives, and recommendations as to the staging or timing of the various proposed steps; and (4) effectuation of the plan, including the carrying out of the responsibilities of the various bodies and agencies concerned with each aspect of the regional development. The first three steps generally involve the planning agency directly; most planning agencies do not have the responsibility of effectuation but rather recommend the necessary steps to the appropriate agencies and at times may suggest the creation of new agencies for specific purposes. Inventory, analysis and the making of the plan involve the efforts of many specialists, and the professional planner is essentially a co-ordinator. Once a plan is prepared and adopted, it is essential, in most instances, that it be subjected to continuous or periodic review and revision in the light of subsequent developments. The continuity of operation of planning agencies is therefore important. The nature of the process of effectuation, of course, varies with the nature of the government

and other institutional operations in the region or for the objectives of the particular plan. In some countries, as in the Soviet Union, effectuation of a plan is by a central authority with absolute powers; in democratic countries the authorities are responsible directly to the public and in many instances the plan or major elements of it may be subject to referendum. In most instances, legislative bodies within areas of appropriate jurisdiction adopt either total plans or the individual proposals contained within the plans. Educational programs and information services on the nature of planning and the objectives and content of specific plans are therefore essential aspects of planning in democratic countries. Most regional planning involves multiple purposes and the regions are demarcated in such a way as to serve the maximum number of purposes with the maximum effectiveness. The conservation movement in the United States in the early 20th century was an important incentive to regional planning; later the multipurpose development of water resources, as in the Tennessee valley and the Columbia basin, constituted an important type of regional planning. Meanwhile, the spread of cities beyond the boundaries of municipalities and the development of metropolitan areas and conurbations became important incentives for another type of regional planning, typified in the United States by the Burnham plan of Chicago, published in 1909, the Regional plan of New York city and its environs, in the 1920s, and the creation of many metropolitan planning agencies in the 1950s, and in Great Britain by the numerous regional planning schemes of the period during and shortly after World War II.

Aspects of Regional Planning.—Much of the concern of regional planning relates to two aspects of man's relations to regional resources. The first may be termed the static aspect, and it includes those features, tangible and intangible, which have fixed locations at any point in time, such as land uses, buildings, population distribution and other features of culture; the second may be termed dynamic and refers to the interchange of people, goods and ideas within and among regions and places, as expressed by transportation facilities and the flows of traffic as well as by communication. No place or region can be completely self-sufficient; each has innumerable bonds with other regions and places. The strength and relative importance of these bonds vary with the size, distance and complexity of the various regions and places and are subject to change with the existence and utilization of alternative opportunities represented by competing regions and places, the possibility of substitution of resources of other places or of other types, changes in the material or intangible cultures of the respective regions, and the competition among alternative routes and forms of transportation. Transportation makes regional specialization possible, and the planning of facilities for the handling of movement to, from, and within regions has become an important aspect of regional planning. In many regions of the world where economic development has been retarded by inadequate transportation facilities, a major concern of regional planning is the selection of appropriate forms of transportation, as between railways, highways, airways and inland and coastal waterways, and the determination of the amount and routes of transportation to be recommended. In the United States, the Federal Highway act of 1956, which provided for a new 41,000-mile interstate highway system, was a stimulus for the organization of regional planning in many areas, as was the focusing of the highway networks upon urban centres and the stimulation of peripheral expansion of population and development within and beyond metropolitan areas as a result of the increased availability of motor transportation.

Regional planning on the one hand is an extension of local planning at the municipal and county level and on the other hand is a part of national and international planning. In the United States regional planning was stimulated in the 1930s by the National Resources Planning board, which was terminated with the advent of World War II. In the second half of the 20th century, however, numerous state planning agencies were in operation, as well as a number of metropolitan and *ad hoc* regional planning agencies.

REGIUM DONUM (ROYAL BOUNTY), an annual grant formerly made from the public funds to Presbyterian ministers in Ireland and to Nonconformists in Great Britain.

In 1690 William III made a grant of £1,200 a year to Presbyterian ministers in Ulster as a reward for their services during his struggles with James II. Agitation, at first unsuccessful, against this grant on the part of certain Church of Ireland clergy, especially William King, archbishop of Dublin, led to its withdrawal toward the end of Queen Anne's reign, but George I revived and increased it (1715). Further increases were made later because the salaries of Presbyterian ministers were much lower than those of Church of Ireland clergy even in areas where Presbyterianism was in the majority. When the Church of Ireland was disestablished in 1869, the *regium donum* was discontinued.

In England during Charles II's reign Presbyterian ministers received an annual pension of £50, and in 1721 Edmund Calamy received £500 "for the use and behalf of the widows of dissenting ministers." But the *regium donum* proper began in 1723 with the annual grant of £500 (soon doubled) paid to nine Nonconformists who divided it among needy ministers and their widows, whether Presbyterian, Baptist, or Independent. Although the sums received by any one individual were small, some dissenters believed that political implications were attached to this royal charity, which they therefore subjected to various attacks almost from its inception. By the middle of the 19th century most Nonconformists had become discontented with it, and in 1851 it was discontinued.

REGNARD, JEAN FRANÇOIS (1655–1709), French dramatist, one of the most successful of Molière's immediate successors. Baptized in Paris on Feb. 8, 1655, he inherited a fortune and traveled widely in his youth (he was a prisoner of the Algerian corsairs for seven months, 1678–79). He held a post in the financial administration in Paris, but from 1688 devoted himself almost entirely to the theatre, writing first for the Italian comedians, then, from 1694, for the Comédie Française. He also published accounts of his travels. Of his numerous plays, the best-known are *Le Joueur* (1696) and *Le Légataire universel* (1708), but *La Sérénade* (1694), *Le Distrait* (1697), *Démocrite* (1700), *Les Folies amoureuses* (1704), and *Les Ménechmes, ou les Jumeaux* (1705) also helped to make his reputation. He imitated both the Italians and Molière quite openly. Regnard died on his estate of Grillon, in Normandy, on Sept. 4, 1709.

There are collected editions of his works by E. Fournier, 2 vol. (1854) and by A. Michiels (1875) and selections ed. by G. d'Heylli, 2 vol. (1886).

See P. Toldo, "Études sur le théâtre de Regnard," *Revue d'histoire littéraire de la France* (1903–04); H. C. Lancaster, *History of French Dramatic Literature in the 17th Century*, part iv (1940).

(W. G. ME.)

REGNAULT, HENRI VICTOR (1810–1878), French chemist and physicist noted for his work on the properties of gases, was born on July 21, 1810, at Aix-la-Chapelle. His early life was a struggle with poverty. He worked in a textile establishment in Paris until 1829 and then entered the École Polytechnique, passing in 1832 to the École des Mines. After studying under Justus von Liebig at Giessen, Ger., he was appointed to a professorship at Lyons. In 1840 he became professor of chemistry in the École Polytechnique in succession to Gay-Lussac and was elected a member of the Académie des Sciences; in 1841 he succeeded Pierre Louis Dulong as professor of physics in the Collège

de France. In 1847 he published a four-volume treatise on chemistry which was translated into many languages. In 1854 he was appointed director of the porcelain manufactory at Sèvres. His laboratory there was destroyed during the Franco-German War of 1870–71, in which also his son Henri, the painter, was killed. Regnault never recovered from the double blow, and, although he lived until Jan. 19, 1878, his scientific labours ended in 1872.

His most important contribution to organic chemistry was a series of researches, begun in 1835, on the halogen and other derivatives of unsaturated hydrocarbons. He also studied the alkaloids and organic acids, introduced a classification of the metals, and effected a comparison of the chemical composition of atmospheric air from all parts of the world. Regnault's work in physics was remarkably accurate and painstaking, and he designed standard types of apparatus for a large number of measurements. He made careful redeterminations of the specific heats of many solids, liquids, and gases. He investigated the expansion of gases by heat, and showed that, contrary to previous opinion, no two gases have precisely the same coefficient of expansion. By delicate experiments he proved that Boyle's law of elasticity of a "perfect" gas is only approximately true for real gases. In his studies of thermometry he introduced the use of an accurate air-thermometer, comparing its indications with those of a mercurial thermometer and determining the absolute expansion of mercury as a step in the process. He also devised Regnault's hygrometer (an instrument for measuring humidity). Regnault's most important work is collected in volumes 21 and 26 of the *Mémoires de l'Académie des Sciences.*

REGNAULT (REGNAUD) (DE SAINT-JEAN D'ANGÉLY), **MICHEL LOUIS ÉTIENNE,** COMTE (1761–1819), French statesman and administrator who held important offices during the First Empire, was born at Saint-Fargeau (Yonne) on Nov. 3, 1761. He became an *avocat* in Paris and later a judge in the maritime provostship of Rochefort. Elected to the States-General (1789) as deputy for Saint-Jean d'Angély, he sat in the centre in the Constituent Assembly and played only a secondary role. Having opposed the Jacobins in the press (1792), he was arrested (1793) in the Terror, but escaped. Hospital administrator for the army of Italy (1796), he embarked for Egypt (1798) with Bonaparte, but stayed at Malta as civil commissioner. Regnault aided Bonaparte in the *coup d'état* of 18 Brumaire (1799) and became a member of the *conseil d'état,* presiding from 1802 over the affairs of the *Intérieur,* and helping to prepare the commercial legal code of 1807. Attorney-general in the high court (1804), registrar in charge of the imperial household, and minister of state (1807), he was created comte in 1808. Out of office during the First Restoration (1814), he was vice-president of the *conseil d'état* during the Hundred Days (1815) and was also elected to the Chamber of Representatives. He encouraged Napoleon to adopt liberal policies and persuaded him (June 1815) to abdicate for the second time. Exiled at the Second Restoration (1815), Regnault lived in the United States and then in Belgium. Authorized to return to France, he died March 11, 1819, the day after he reached Paris. (C. E. DU.)

RÉGNIER, HENRI FRANÇOIS JOSEPH DE (1864–1936), the foremost French poet of the first decade of the 20th century, was born at Honfleur on Dec. 28, 1864, of an old Norman family. Going to Paris to study law, he came under the influence of the Symbolist poets there. His first books of poems, *Lendemains* (1885), was followed by several other minor collections, eventually reprinted in two volumes, *Poèmes 1887–1892* (1895) and *Premiers poèmes* (1899). In 1896 he married the poet J. M. de Heredia's daughter Marie, herself later well known as a poet under the pseudonym Gérard d'Houville.

By this time Régnier showed a preference for themes from classical antiquity or from the Renaissance, so that while the personal quality of his approach and certain metrical licences still reflected the Symbolist influence, his subject matter came to be more like that of his Parnassian father-in-law. His most characteristic poems in this style appeared in *Les Jeux rustiques et divins* (1897), *Les Médailles d'argile* (1900), *La Cité des eaux* (1902), mainly about Versailles, *La Sandale ailée* (1906), and *Le Miroir des heures* (1910). His aristocratic manner distinguished him from his more bohemian contemporaries, and he became the favourite poet of *la belle époque.* He was elected to the Académie Française in 1911 (received 1912).

Régnier published some patriotic verse in *1914–1916* (1918), but his only major collections of poems after World War I were *Vestigia flammae* (1921) and *Flamma tenax, 1922–1928* (1928). From 1894, however, Régnier had been publishing also novels and short stories, in which he combined realism with a hedonistic attitude to morality. These include *Contes à soi-même* (1894; reprinted in *La Canne de jaspe,* 1897), *La Double Maîtresse* (1900), *La Peur de l'amour* (1907), *L'Amphisbène* (1912), *Romaine Mirmault* (1914), *La Pécheresse* (1920), *Le Divertissement provincial* (1925), and *Le Voyage d'amour* (1930). Henri de Régnier died in Paris on May 23, 1936.

RÉGNIER, MATHURIN (1573–1613), French satirist, whose acute power of observation was turned on the daily life of his time, and whose language was rooted in the speech of the people. He was born at Chartres on Dec. 21, 1573, the son of Jacques Régnier, a magistrate, and Simone, sister of the poet Philippe Desportes. Little is known of his early years except that he received the tonsure at eight and later became a secretary of Cardinal François de Joyeuse, accompanying him to Rome in 1587. After years of irksome duties and travel, on returning to France about 1605, he accepted Desportes' protection. In 1606 Desportes died and Régnier obtained a pension of 5,000 livres chargeable on one of Desportes' benefices. In 1609 he was made canon of Chartres through his friendship with the bishop, Philippe Hurault, at whose abbey of Royaumont he spent much of his time in his remaining years. He died at Rouen on Oct. 16, 1613.

His works include regular satires in alexandrine couplets, serious poems in various metres; the authenticity of the epigrams and light pieces published after his death and attributed to him is doubtful. His real greatness consists in the verve and realism of his satires, in which he depicts typical characters of the time. He recalls Horace, Juvenal, Ariosto, the Italian *bernesci* poets, and Ronsard, but his imitation is free and original. His dialogues, his narrative, and his characterization are full of life and picturesque detail, and his language is down to earth, colourful, and rich in colloquial idioms and expressions. He was an acute critic, and the famous passage in which he castigates François de Malherbe (Satire IX, *À Monsieur Rapin*) is a brilliant attack on the purist poetic theory and its conformity with precise classical and intellectual standards. His talents are fully displayed in the satiric masterpiece, *Macette,* a work that can stand comparison to Molière's *Tartuffe.*

BIBLIOGRAPHY.—*Works: Les Premières Oeuvres de Régnier* (1608) includes the *Discours au roi* and ten satires. Editions in 1609, including 12 satires; 1612, including *Macette;* and 1613, were followed by *Les Satyres et autres oeuvres folastres du sieur Régnier* (1616), with many additions, some by other hands; and by two famous editions by Elzevir (1642, 1652). *Oeuvres,* ed. by C. Brossette (1729), contains a standard commentary on Régnier. Later editions include those by E. Courbet (1875), which follow the first editions; *Oeuvres complètes,* ed. by J. Plattard (1930), and by G. Raibaud (1958).

Scherer, "Les satires posthumes de Régnier," in *Revue d'histoire littéraire* (1947); O. T. Rossettini, *Les influences anciennes et italiennes sur la satire en France au XVI^e siècle* (1958). (RA. L.)

REGNITZ, a river of south Germany and left-bank tributary of the Main. The river upstream to the confluence of the Pegnitz, 42 mi. (68 km.), is called the Regnitz; its southerly extension, 22 mi. (35 km.), is known as the Rednitz, which is formed by the confluence at Georgensgmünd of the Swabian and Franconian Rezat. Its main course, from south to north, flows across a lowland of sandstones and clays. Pine forest covers most of the area. The vine is absent, but hops are important and account for the Nürnberg brewing industry. The river passes the towns of Fürth, Erlangen, and Forchheim, from which point it is navigable. It joins the Main just below Bamberg. The old and inadequate Ludwig Canal connects the Main and the Altmühl, a tributary of the Danube. A new canal was under construction in the 1960s from Bamberg, parallel to the Regnitz, through Nürnberg and

thence, alongside the Ludwig Canal, to the Danube; it was due for completion in 1969. (R. E. Di.)

REGULATORY AGENCIES. Administrative regulation is a basic feature of 20th-century government that sharply distinguishes it from government in the 19th century. Formerly governmental regulation was provided for almost entirely by statutes, whose prescriptions were enforced through the traditional machinery of the courts. Such legislative regulation proved inadequate to deal with the complexities of a modern industrial economy. In its place, there developed a system of administrative regulation. Under it, the legislature provides only the broad principles of a particular regulatory scheme, leaving their detailed implementation to the agency charged with administering the law. The latter is vested with the power to prescribe regulations having the force of law, to police those subject to its authority to ensure that such regulations are not violated, and to decide cases involving alleged particular violations. The administrative agency is able to furnish the continuous supervision and expert knowledge that cannot, as a practical matter, be expected of the legislature.

United States.—The need for administrative regulation first became apparent in the United States in the railroad industry, and it was out of the attempts to deal with the railroad problem that the first modern U.S. administrative agency, the Interstate Commerce commission (ICC), was developed. Established by the Interstate Commerce act of 1887 and with its power expanded by the Hepburn act of 1906 and subsequent statutes, it is composed of 11 members appointed by the president, and confirmed by the senate, who serve for staggered terms of seven years. The commissioners may be removed only for cause and have, in practice, been able to function free from direct presidential control. This has led some to characterize them as a "headless fourth branch" of the government.

ICC is the classic example of a quasi-judicial regulatory agency. As such, it applies the broadly stated legislative policies to concrete cases by a procedure patterned upon that of the courts. The commission fixes reasonable rates and ensures that they are observed. It grants licences to those seeking to engage in interstate transportation. It exercises injunctive power over discriminatory practices. The commission also performs important nonjudicial functions. It promulgates safety and other regulations. It controls railroad financing and planning. It is the commission which gives specific form and content to the congressional policies expressed in the Interstate Commerce act as amended. Its position has been compared to that of a superboard of directors of the railroad industry. It also has extensive authority over motor carriers. (*See* also INTERSTATE COMMERCE.)

The assertion of governmental control in other economic fields led to the creation of many other regulatory agencies modeled upon the ICC, chief among these being the Federal Trade commission (FTC; 1914), Federal Power commission (FPC; 1920), Federal Communications commission (FCC; 1934), Securities and Exchange commission (SEC; 1934) and Civil Aeronautics board (CAB; 1938). (*See* COMMISSION.) In addition, regulatory powers were conferred upon the ordinary executive departments; *e.g.*, the department of agriculture under the Packers and Stockyards act, 1921, and the Agricultural Adjustment act, 1938. As traditional legal devices proved inadequate to cope with economic abuses, they were superseded by administrative controls. This was especially true of the period following the depression of the early 1930s. The New Deal program was largely carried out through administrative regulation. During the same period, a comparable development took place in the states.

Other Countries.—Administrative regulation is not a purely U.S. phenomenon. Similar problems have given rise to the creation in other countries of some analogous regulatory agencies. In England the starting point was the setting up of the Railway and Canal commission in 1888. In 1921 the Railway Rates tribunal was established to fix railroad rates. After the nationalization of British railways in 1947 the British Transport Commission (BTC) was established to assume control of Britain's railways, canals, and certain other means of transport. It was a policy-making agency, not a managing body, and was dissolved in 1962 in favour of separate boards for railways, London transport, docks, and waterways.

There is an important difference between administrative authority in the United States and that in other countries. Administrative regulation is basically of two kinds. In certain fields the normal rules of free competition are recognized to be inapplicable. In them, the state tolerates the existence of virtual monopolies, but by regulation it ensures that the monopolistic power shall not be abused. This is the usual practice regarding public utilities. In other areas, free competition governs but the state intervenes to prevent abusive practices conceived deleterious to the working of a free competitive system. Thus, the FTC was established in the United States to prevent unfair trade practices.

In other countries, there is less room for these types of administrative regulation than in the United States. In the field of public utilities the dominant theme is not regulation but operation. Toward abusive practices other governments also tend to adopt more of a hands-off policy than does the U.S. This applies in both Britain and in continental European countries, though less so in the former in view of the specific types of British regulation already mentioned, as well as the setting up in 1948 of a Monopolies and Restrictive Practices commission patterned upon the U.S. Federal Trade commission.

Abuses of Administrative Power.—Administrative regulation enables government to cope with the need to control economic power in the public interest. But at the same time it raises the basic problem of whether the regulator himself is adequately controlled; the executive and legislature are responsible to the people but the administrator has no similar responsibility. In democratic countries, he is, it is true, responsible to the law, but this "rule of law" becomes less effective under statutes delegating wholesale discretion. Under such "skeleton" legislation, the flesh and the blood (not to mention the soul) of regulation are left to the administrator. Excessive discretion opens the door to administrative arbitrariness.

The growth of administrative regulatory power was accompanied by the development of safeguards to ensure against administrative abuses. In the U.S. the emphasis is upon procedural devices and judicial review. Due process (*q.v.*) requires that, before administrative action adversely affects an individual, he be given notice and a full opportunity to be heard. Such hearings must include the essentials (though not the forms) of judicial procedure. The fundamentals of fair administrative procedure were prescribed in the Federal Administrative Procedure act, 1946, and in similar laws in many states. Those aggrieved by administrative action can obtain review in the courts. In Anglo-American countries such review is in the ordinary courts. In France and many civil-law countries there is a special administrative-court system to review the legality of administrative action. There is also legislative control. This is most fully developed under parliamentary systems; *e.g.*, in Britain, where administrative regulations are subject to direct annulment by parliament. In the United States, control by the congress did not prove effective in practice, though attempts were made to remedy the situation in the Legislative Reorganization act, 1946, by giving standing congressional committees direct responsibility over administrative agencies. This did not prove workable because of the preoccupation of such committees with other matters and their lack of adequate staffs.

REGULUS, MARCUS ATILIUS, Roman general and consul first in 267 B.C. and again in 256 B.C. when with his colleague he defeated the Punic fleet at Ecnomus and landed an army

in Africa (*see* PUNIC WARS). When the other consul was recalled, Regulus was left to finish the war. After a severe defeat at Adys near Carthage, the Carthaginians were inclined for peace, but the terms proposed by Regulus were so harsh that they resolved to continue the war. In 255 he was defeated and captured. According to tradition, he remained in captivity until he was sent to Rome on parole to negotiate a peace or exchange of prisoners (250); he urged the Senate to refuse both proposals and, returning to Carthage, was tortured to death. The story, insufficiently attested, was possibly invented to excuse the treatment of Carthaginian prisoners at Rome. It served to make Regulus a model of heroic endurance to the later Romans.

See E. Klebs in Pauly-Wissowa, *Real-Encyclopädie der classischen Altertumswissenschaft,* ii, 2086–92 (1896). His fate is celebrated in Horace, *Odes,* iii, 5.

REHABILITATION, MEDICAL AND VOCATIONAL. Rehabilitation is the help and training given to a sick or handicapped person to enable him to live as full a life as his remaining abilities and degree of health will allow. The emphasis is first on the medical aspects, later on physical therapy and occupational therapy (*qq.v.*), and finally on the vocational and social aspects.

Successful rehabilitation inevitably involves not only the body but mind and spirit as well. It is the function of the rehabilitation team to support the patient and help him find satisfaction in life by understanding his physical handicap and associated psychological difficulties. In most instances the handicapped person must be retrained to walk and travel, to care for his own daily needs, to apply and remove his own prosthetic devices, to communicate orally or in writing, and eventually to find a useful place in society. Success in solving his most immediate problems goes a long way toward eliminating the patient's fear of falling out of the accepted pattern of life. Anxiety about his state and capabilities may set back a patient's chances of recovery; therefore the rehabilitation team must allay not only his own fears but also those of his family. The patient with a serious residual disability should be encouraged to accept his handicap and his consequent dependence upon others; but such encouragement should not be extended to the patient who clings to a remediable disability as an emotional excuse to justify dependence and to free himself from worries and responsibilities.

MEDICAL REHABILITATION

Physical Handicaps.—Handicaps can be inherited or they can result from accidents, disease, birth injury, or the degenerative changes of old age. In the United States it has been estimated that 88% of physical disabilities are due to disease (particularly chronic disease), 10% to accidents, and 2% to congenital malformation. A considerable proportion of persons handicapped by physical deficiency or mental subnormality are suffering from a congenital defect, either inherited or resulting from intrauterine factors or difficulties at birth.

Diseases of the joints are the most common crippling diseases. Rheumatoid arthritis and osteoarthritis both attack women more frequently than men, and elderly women most frequently. Both diseases are painful and progressive; and, even after treatment, deformity, stiffness, and limitation of movement almost invariably persist. The loss of sight, hearing, and touch also require extensive rehabilitation.

Hemiplegia (paralysis of one side) after a stroke is a major cause of disability, particularly in North America and northern Europe. For persons who survive six to eight weeks after the initial stroke, life expectancy is the same as for others of their age. Treatment starting as soon as the patient recovers consciousness prevents the stiffening of the joints on the affected side and the contractures, especially at the shoulder, which are the usual result of an attack.

Paraplegia (paralysis of the lower limbs) below a severance of the spinal cord may result from war wounds, automobile accidents, surfing and diving accidents, or disease. Training with crutches can help some paraplegics to lead noninstitutional lives; a few are able to walk in braces (splints).

Medical rehabilitation can do much to overcome spasticity (stiffness and spasms) and the sensory disorders and mental retardation in young children caused by cerebral palsy. Multiple sclerosis, attacking those between the ages of 20 and 40, is progressive and unpredictable; hence it is difficult to anticipate training ahead of the progress of the disease. Rehabilitation can produce good results in patients with chronic arthritis, pulmonary disease, epilepsy, the chronic degenerative neurologic diseases, and heart and circulatory ailments. Some babies are born deficient in limbs. Special measures are taken at the earliest opportunity to fit them with appropriate prostheses (artificial limbs) which they learn to operate by trial and error in the same way that a normal infant discovers the use of his limbs. Loss of limbs following accident or surgical operation is similarly compensated for by prosthesis. (*See* PROSTHETICS.)

Psychiatric Handicaps.—The psychoneurotic person may have a flawlessly functioning body and the will to become whole, but his mind is sick. He is usually isolated emotionally from his fellow man; rehabilitation is designed to break down the barriers he has erected around himself. At the mental hospital participation in social activities is part of his treatment, and toward the end of his stay weaning from the protective hospital aura takes place gradually. The patient is helped to find employment outside the hospital by day, returning there to be under psychiatric supervision in the evening and on weekends. Later still he may live at home and attend evening group sessions once or twice a week to discuss with fellow patients and with the psychiatrist the problems he encounters. An inadequate personality may need psychotherapy (*q.v.*) of a supportive kind for most of his lifetime.

Alcoholism (*q.v.*) is not wholly a psychiatric disorder, and few habitual heavy drinkers are addicts. Most can break the habit fairly easily; the addict cannot without terrible suffering, and consequently needs rehabilitation.

Treatment.—The first step in rehabilitation is to ensure that the patient is receiving adequate and appropriate medical or surgical treatment. It is particularly important to know whether his disease is (1) permanent, but nonprogressive and nonfatal; (2) fluctuating, but not immediately endangering life; or (3) steadily progressive, and, if so, the likely speed of progression, as this will affect the goal of rehabilitation.

Details of treatment depend on the nature of each patient's disability and his personality, physical condition, background, and likely future life; but group treatment is often given as well. The daily programs are made up of periods of exercises, physical and occupational therapy oriented to realistic occupations, and rest. The rehabilitation of heart and lung cases, for example, involves carefully graduated exercise, checked periodically by exercise tolerance tests. Each day the patient is encouraged to attempt one-fifth more than he did on the previous day. Few, however, achieve such uninterrupted progress; many have to mark time, repeating the previous day's prescription until it is performed with confidence before extending exertions further. Often an inexorable "upper limit" becomes apparent; the patient may then go home, having learned by experience the true extent of his limitations but confident that, provided he lives within them, all should be well. Rehabilitation centres also prescribe, fit, and (in some countries) supply aids such as hearing devices, prostheses, and invalid chairs.

Independence in Daily Life.—The patient must be taught to cope single-handedly with his daily needs, and a great deal can be done to help him to adjust to his old environment or to modify it. A hemiplegic may be helped by the provision of an electric razor and by modification of his clothing; *e.g.,* by the substitution of zippers for buttons, elastic-sided shoes for lace-ups, and clip-on bow ties for ties that must be knotted. "Lazy tongs" or spring-grip clothespins attached to the ends of rods about two feet long may enable an arthritic patient to pull stockings over feet his hands cannot reach. A banister rail fixed to the wall on the patient's "good" side will help him mount stairs, and a grip rail on each side of the lavatory seat will help him to rise from it unaided. A "nonslip" mat at the bottom of the bath and a webbing strap across its top can enable a patient to climb out by himself.

Retraining for the disabled housewife, including the provision of special kitchens and other equipment, started in the United States (1948) and spread to Great Britain (1950), where it is carried out by the occupational therapy departments of the National Health Service hospitals.

In Great Britain medical social workers (almoners) help the patient to overcome immediate domestic anxieties and will later help in reconciling him and his family to his new condition. There are hostels for patients who cannot live at home and for those who have had a serious mental illness. Social workers will help to adapt the home (*e.g.*, by putting in ramps for a wheelchair); arrange for home nursing; and sometimes provide domestic assistance. Such assistance is part of the National Health Service, and the patient is charged, according to his means, up to a maximum.

Programs and Facilities.—In the United States, federal-state action to eliminate or reduce a handicap through medical services was first authorized by federal legislation in 1943. Care is provided through public agencies in all states, and services offered include medical and surgical treatment. Prosthetic devices are offered where the patient's condition is stable, a favourable outcome may be expected within a reasonable period of time, and financial need has been demonstrated. This approach is taken in several other countries, including Australia and Canada.

In Great Britain, medical rehabilitation facilities are provided under the national health plan in departments of physical medicine and occupational therapy at the main hospitals and in a few special centres. For the minority of patients with a multiplicity of problems some hospitals run settlement clinics. Paraplegics at the Spinal Injuries Centre, Stoke Mandeville, Buckinghamshire, are encouraged to join in modified athletic contests founded there in 1948. These games, which became international in 1952, were held in Rome in 1960 and in Tokyo in 1964, after the Olympic Games; hundreds of paraplegics from many countries competed in events such as wheelchair skiing, weight lifting, and fencing. An international sports meeting open to all disabled was held at Linz, Aus., in 1963.

Denmark gives state support to voluntary hospitals and clinics through social insurance or financial assistance to patients, and pays for the transport of outpatients to the clinics. In West Germany, where much importance is attached to sport and exercises for the disabled (including spastics), the government sponsors courses for the handicapped of all nationalities held by the German Sports Association for the Physically Handicapped, which also cooperates with the Ministry of Labour and the Ministry of the Interior. In the U.S.S.R., the Ministry of Social Welfare provides free sanatoriums, rest homes, and prostheses.

VOCATIONAL REHABILITATION

During the patient's rehabilitation, it must be decided whether he will be able to go back to his previous job. If this is impossible he may be taught new skills for a more suitable job; or he can take up some remunerative hobby pursued at home in his chair or even in his bed. The emphasis throughout is on self-help and on productive work—not entirely from financial considerations but because self-help maintains self-respect and affords an outlet for the creative drive, while productive work is more pleasurable for most people than enforced idleness.

Extent of the Problem.—Worldwide information about the number of persons who require vocational rehabilitation is meagre. In the United States it was estimated that in 1965 there were approximately 20,000,000 persons, exclusive of those in institutions, who were handicapped to some extent by chronic illness; of these, 4,000,000 were totally unable to carry out their major activity (working, keeping house, going to school). In Great Britain in 1965 there were about 655,000 persons registered with the Ministry of Labour as disabled; on any one day there were 95,000 persons who had been off work for six months or longer. A census in Canada and another in France showed that about 1% of the population aged between 16 and 64 was unable to work. If to these estimates are added the handicapped children, the chronically sick, the handicapped who are at work, and the handicapped in retirement, a rough minimum estimate might be that the handicapped make up 5% of these populations. It is not suggested that all these people need rehabilitation, although estimates indicate that between 10 and 20% of all patients discharged from hospitals would benefit from it. The figure varies with the type of case, being highest for orthopedic, neurological, and rheumatic cases and lowest for general surgical cases.

It is important that the type and extent of training given be correlated with the level of general education and the opportunities for employment in a given locality. In less developed countries, priority should be given to the preventive medical services, the building up of the curative services, and the training of staff before ambitious rehabilitation programs are started.

ORGANIZATION OF SERVICES

The first specialized rehabilitation centres were set up toward the end of the 19th century. In the United States the Cleveland Rehabilitation Center was founded in 1889 and the Red Cross Institute for the Disabled (now the Institute for the Crippled and Disabled) followed in New York City in 1917. In Britain Dame Agnes Hunt, herself crippled from the age of ten, started the first convalescent home for cripples in 1900 and the first aftercare clinics in 1907. The problems of the disabled serviceman led to interest in expanding the rehabilitation services; during World War I, Sir Robert Jones established a series of rehabilitation departments in British military hospitals, and during World War II the Royal Air Force and the U.S. Veterans Administration, in particular, established first-class rehabilitation services. Interest was also heightened by the increase in age of the population in many parts of the world. In developed countries rehabilitation services for the handicapped prospered with an expanding consciousness of the need for social welfare work. In the 1950s there was a growth of rehabilitation and training centres with improved physical and occupational therapy; so that, for example, North America, Eastern and Western Europe, and the Middle East were all represented at an international conference on vocational rehabilitation in 1962.

In its early years vocational rehabilitation consisted largely of attempts to get around the patient's disability by specialized job training and by helping him to find work, with little emphasis on medical services. By the 1960s, however, some public and private industries had set up special workshops for their own convalescent and injured employees, often in conjunction with the local hospital service; and sheltered working conditions were provided for infectious tuberculosis patients or those with grave mental or physical difficulties.

United States.—After World War I the U.S. government and the states worked together to provide vocational rehabilitation services for persons who could be made employable. Studies show that the federal government recouped in income taxes alone ten dollars for each dollar invested in such services. This program in 1964 rehabilitated approximately 120,000 persons, whose individual earnings were increased, on the average, by $1,750 a year.

The state-federal program of vocational rehabilitation in the U.S. as authorized by the 1954 act amending the 1943 act is primarily concerned with disabled persons who can become economically independent. Its objective is to place them in gainful employment in offices, stores, and factories, in sheltered workshops, or at home. Services are also extended to persons who contribute to the national economy in other ways (*e.g.*, homemakers). The program is organized and administered as a state-federal partnership. Federal responsibilities are discharged by the Vocational Rehabilitation Administration (VRA) of the Department of Health, Education, and Welfare. Federal grants are made to states to help pay for existing rehabilitation programs and to encourage the states to offer new services and extend coverage to new localities. VRA also conducts investigations and disseminates information on the needs and capabilities of the handicapped. Regional representatives of the department can be consulted on specialized aspects of rehabilitation, and they assist the states in interpreting their programs to the public. Actual services to the disabled are provided in all states by public agencies, each working out its individual plan with the federal office. Besides physical

restoration, services include the supply of occupational tools, initial stocks of goods for small business enterprises, job placement, and follow-up. The use of public funds for services other than medical diagnosis, counseling, placement, and follow-up depends on the economic status of the client. In the 1960s, physical restoration services were received by more than half of the persons rehabilitated in the U.S., and accounted for more than 40% of the expenditure for casework.

Great Britain.—The Disabled Persons (Employment) Act (1944) is the basis of all vocational rehabilitation. Disablement resettlement officers (DROs) are employed by the Ministry of Labour and work from the local employment exchanges both to help handicapped people find work and to build contacts between employers and hospitals. Under the "quota" plan employers are required to engage a proportion of disabled drawn from the ministry's registered list. Registration is voluntary, and many disabled persons do not register; the DRO may even discourage a patient from registering if he thinks that, for him, the psychological effect of being officially categorized "disabled" may be so bad as to outweigh the practical advantage of his easier placement in a job. The direction of a patient to an occupation reserved for the disabled also may have psychological disadvantages.

Industrial rehabilitation and vocational guidance are provided at both residential and nonresidential units run by the Ministry of Labour. Other types of vocational training are given in government training centres, educational institutions, and employers' establishments. For the more seriously disabled, special residential training colleges, such as the Queen Elizabeth Training College for the Disabled at Leatherhead, Surrey (founded 1935), run by voluntary organizations with financial assistance, offer help for special categories, such as the blind. Patients who cannot leave their homes may have work brought to them. Sheltered employment in the 1960s was provided for about 6,300 by a nonprofit company, Remploy Ltd., whose directors are appointed by the Ministry of Labour and which is supported by loans and grants from the Ministry of Labour.

Other Countries.—Elsewhere in Europe arrangements are similar to those in Great Britain. In Denmark, for example, therapists, job specialists (*e.g.*, engineers), vocational guidance experts, and employment exchanges cooperate to achieve for the disabled employment conditions as near normal as possible. In the U.S.S.R. the Ministry of Social Welfare retrains the handicapped and obliges employers to give them suitable work and conditions, while special medical commissions supervise them and research institutes study their labour problems. Austria, France, Germany, Greece, and Israel have "quota" arrangements for employment of the handicapped.

In underdeveloped nations the restoration of the disabled made great strides after World War II with an increased amount of government, voluntary, and Christian-mission work and with the help of agencies of the United Nations, especially the World Health Organization (WHO) and the International Labour Organization (ILO). For example, in India, Pakistan, and a number of African and Latin-American countries the governments subsidize UN and ILO projects or run projects that receive UN and ILO help. These include training programs for physiotherapists, psychiatrists, and nurses for hospitals and clinics (many of whom are given studentships with which to qualify in Europe); prosthetic and orthopedic services; and simplified agricultural training for the rural blind.

Throughout the world the amount and kind of governmental organization vary from the highly centralized Mexican system to the cooperative relation between government and local authorities, as in Canada. France has an interministerial committee for the disabled; Japan's rehabilitation programs, for both adults and children, are administered by the Ministry of Health and Welfare. Voluntary bodies sometimes have their own cooperative organization and sometimes coordinate their efforts through national councils established by the various governments. This latter system is recommended by WHO and ILO. The Conference of World Organizations Interested in the Handicapped (CWOIH) has 30 member organizations, mostly of consultative status with the UN Economic and Social Council.

REHOBOAM, last king of the united kingdom of Israel and first king of the southern kingdom of Judah, son and successor of Solomon, began to reign *c.* 934 (or 922) B.C. The events are related in I Kings 11–14 and II Chron. 10–12. Rehoboam was not acceptable to the northern tribes, who recalled Jeroboam (*q.v.*) from his exile in Egypt and made Rehoboam's contemptuous refusal of their demands the occasion for instituting a rival kingdom under Jeroboam (I Kings 12). It is probable that this was done with the encouragement of Egypt. Sheshonk I (Shishak) of Egypt attacked the kingdom of Judah and despoiled the temple at Jerusalem of its treasures. Rehoboam's reign was marked by constant conflict with the northern kingdom of Israel. An unfavourable judgment is pronounced on him by the editor of Kings because he favoured customs connected with Baal worship. The fact that his mother was an Ammonite woman may in some measure account for this. He was succeeded after a reign of 17 years by his son Abijah (in I Kings, Abijam), of whom little is known save a victory over Jeroboam.

REHOVOT ("enlargement"), a municipal town in the Plain of Sharon, Israel, lies 13 mi. (21 km.) SSE of Tel Aviv–Jaffa. It was founded in 1890 as an agricultural village by immigrants from Tsarist Russia. Pop. (1961) 29,003. It is the centre of a flourishing region of citrus orchards and has a large packing station. Chaim Weizmann (*q.v.*), first president of Israel, had his residence there during the British mandate period; the house has been preserved under a trust, and he is buried in the garden. He made Rehovot famous by founding an institute of scientific research in 1934, which became the Weizmann Institute of Science in 1949 and is an important centre of fundamental and applied research. The Faculty of Agriculture of the Hebrew University and the state agricultural experimental station are also at Rehovot. Manufactures include plastics and pharmaceutical products. (No. B.)

REICHENAU, an island in the Untersee (western arm of Lake Constance) in the *Land* (state) of Baden-Württemberg, Federal Republic of Germany. The island is 3 mi. long and 1 mi. broad, its eastern end being connected to the mainland by a causeway $1\frac{1}{4}$ mi. long. Pop. (1961) 4,047. Fruit and flowers are grown and wine is produced. The richly endowed Benedictine abbey of Reichenau, founded in 724 and secularized in 1803, was a famous centre of the arts in the early Middle Ages. The abbey church at Mittelzell (built mainly in the 10th and 11th centuries, with a Late Gothic choir) contains the tomb of Charles III the Fat (d. 888) who retired to Reichenau after being dethroned. A school

of painting flourished there *c.* 1000, the wall paintings in the Romanesque church at Oberzell being the oldest in Germany (10th century). Reichenau is a resort and centre of excursions on Lake Constance. (A. F. A. M.)

REICHENBACH, GEORG VON (1772–1826), German astronomical instrument maker, was born at Durlach in Baden on Aug. 24, 1772. By 1796 he was engaged in the construction of a dividing engine. In 1804 he was one of the founders of an instrument-making business in Munich; and in 1809 he helped establish an optical works at Benediktenbeuern which was later moved to Munich. He withdrew from both enterprises in 1814, and was instrumental in establishing a new optical business, from which he retired in 1820. He died at Munich on May 21, 1826.

Reichenbach built for F. W. Bessel in 1819 an instrument in which he introduced the meridian or transit circle, combining the transit instrument and the mural circle into one instrument. This combination had been introduced earlier, but with the exception of the transit circle constructed by Edward Troughton in 1806, had not been adopted. Reichenbach's form of instrument came into general use. (S. C. Hr.)

REICHENBACH, a town of East Germany in the Karl-Marx-Stadt *Bezirk* (district) of the German Democratic Republic. It lies in the Vogtland, 11 mi. (18 km.) SW of Zwickau. Pop. (1962 est.) 29,359. The earliest mention of the town occurs in a document of 1212; it acquired municipal rights in 1271. Woolen manufacture was introduced in the 15th century and took the place of the mining industry which had been established earlier. Reichenbach has an important textile industry, a textile engineering school, and machinery factories. The serious destruction that occurred in World War II has for the most part been repaired.

REICHSTADT, NAPOLÉON FRANÇOIS JOSEPH CHARLES, Duke of (1811–1832), titular king of Rome from 1811 to 1814, was the Napoleon II of the French Bonapartists, who also referred to him as *le Fils de l'homme* ("the Son of the Man") and as *l'Aiglon* ("the Eaglet"). He was born in the Tuileries Palace in Paris on March 20, 1811, the only son of the emperor Napoleon I and the empress Marie Louise (*qq.v.*). As the long-desired heir to his father, he was styled king of Rome, partly because the elected heirs of the Holy Roman emperors had been styled kings of the Romans. When his father's power was collapsing (*see* Napoleonic Wars), his mother took him from threatened Paris to Blois (April 1, 1814), but his father's offer to abdicate in his favour was superseded by abdication in the name of both father and son, and Marie Louise rejected the proposal of his uncles Jérôme and Joseph (*see* Bonaparte) that he should be taken south of the Loire as the figurehead of further resistance or as a counter for bargaining with her Austrian kinsmen. He was taken instead to the court of her father, the Austrian emperor Francis I. Bonapartist plans for bringing him back to Paris during the Hundred Days (1815) came to nothing.

By the Treaty of Paris (1817) the prince was excluded from eventual succession to his mother's Italian dominions (*see* Parma and Piacenza, Duchies of). Instead he received the Austrian title of duke of Reichstadt (1818). Francis I cherished him, but foreign policy necessitated the duke's remaining under Austrian tutelage. Grieved by his father's humiliation and by revelations of his mother's later conduct, the duke dreamed persistently of some new sovereignty, especially in 1830, when revolutions overthrew Charles X's rule in France and Dutch rule in Belgium; but Metternich's hint that he might be made king of Italy was uttered only to deter the France of Louis Philippe from Italian enterprises. The military exercises that the duke passionately enjoyed were interrupted by ill health, which culminated in pulmonary tuberculosis. He died at Schönbrunn on July 22, 1832. The pathos of his existence is well brought out in Edmond Rostand's masterpiece, *L'Aiglon.*

See E. von Wertheimer, *Der Herzog von Reichstadt,* 2nd ed., 1913 (Eng. trans. of 1st ed., 1905); J. de Bourgoing, *Le Fils de Napoléon,* 2nd ed. (1950).

REICHSTEIN, TADEUSZ (1897–), Swiss chemist and Nobel laureate, was born at Wloclawek, Pol., on July 20, 1897. He shared with E. C. Kendall and P. S. Hench the 1950 Nobel Prize for Medicine for discovering the structure and biological effects of the suprarenal cortex hormones. He was educated at Zürich, where he obtained degrees in chemical engineering (1920) and organic chemistry (1922). He was engaged at first in industrial chemical research, but from 1930 onward he held posts in the department of organic chemistry at the Federal Institute of Technology, Zürich. In 1938 he was appointed head of the department of pharmacology and director of the Pharmacological Institute of the University of Basel, where in 1946 he became head of the organic division and director of the organic laboratories. His investigations were mainly concerned with steroids, particularly the hormones of the adrenal cortex, 26 of which he and his associates isolated. One of these hormones, isolated and described by Reichstein in 1936 and named by him "Substance Fa," proved to be identical with Kendall's "Compound E," and was later renamed cortisone (*q.v.*). Apart from these researches, Reichstein's best-known work is the synthesis of ascorbic acid (vitamin C), which he carried out independently of Sir Walter Norman Haworth and his co-workers, in 1933. (W. J. Bp.)

REID, THOMAS (1710–1796), Scottish philosopher, was the critic of David Hume's skeptical empiricism and the first exponent of the so-called philosophy of common sense continued by the "Scottish school" (*see* Common Sense, Philosophy of). He was born on April 26, 1710, at Strachan, Kincardineshire, the son of Lewis Reid, a minister, and his wife, Margaret Gregory, who belonged to the famous family of mathematicians. (James Gregory [*q.v.*] was Thomas Reid's great-uncle.) He was educated at Marischal College, Aberdeen, and after studying theology and being licensed for the ministry in 1731, remained at Marischal College as librarian from 1733 to 1736. From 1737 he held the living of New Machar, near Aberdeen, for 14 years, during which period he was aroused by his study of Hume's *Treatise of Human Nature* (1739) and began his lifelong task of examining its doctrines (*see* Hume, David). In 1751 he was elected to the chair of philosophy in King's College, Aberdeen, where he remained until in 1764 he succeeded Adam Smith as professor of moral philosophy in the University of Glasgow. During the tenure of his post at Aberdeen, he devoted himself to the problems of epistemology raised by Hume. Reid offered the preliminary results of his examination in four graduation addresses delivered to the university (*Philosophical Orations,* first edition by W. R. Humphries, 1937), which were more fully developed, with special reference to problems of perception, in his first book, *An Inquiry into the Human Mind, on the Principles of Common Sense* (1764). Further deliberation at Glasgow resulted in the *Essays on the Intellectual Powers of Man* (1785; new edition by A. D. Woozley, 1941), their scope being wider than that of the earlier work, and in the *Essays on the Active Powers of Man* (1788), in which he upheld a rationalist theory of ethics against the current subjectivism of Francis Hutcheson and Hume. His only other publications were "An Essay on Quantity" (in the *Transactions* of the Royal Society, 1748), *A Brief Account of Aristotle's Logic* (1774), and the posthumous *Statistical Account of the University of Glasgow* (1799). He died on Oct. 7, 1796, four years after the death of his wife and cousin, Elizabeth, whom he had married in 1740.

Brought up himself on the theory of ideas (the theory that ideas alone are the direct objects of the mind's awareness) and starting out as a Berkeleian (*see* Berkeley, George), Reid was shaken out of his acceptance of this orthodoxy by realizing, as he thought, the skeptical lengths to which the theory led in Hume; for it appeared to deprive us of the possibility of knowing almost all that Reid felt convinced that we do know. Finding himself unable to accept Hume's conclusions or to refute the arguments by which they were reached, he set himself to examine the premisses from which the arguments started, namely the theory of ideas, and came to the conclusion (at the time bold and original) that the theory was based on no better ground than the prejudices and confusions of philosophers. Against the supposition that the immediate data of perception are ideas or in any way peculiarly mental he argued (1) that it is pure hypothesis, unsupported by evidence; and (2) that it does not perform the function for which it was introduced, since its only result is to leave all questions about the veracity of

any perception in principle unanswerable. The latter objection would apply only to a representationalist theory such as Locke's; the former would apply to Berkeley and Hume as well, if Reid's interpretation of them was correct. Reid himself propounded a view of perception which might be called indirect realism. According to this, our senses provide us with immediate sensations (which are neither veridical nor nonveridical), plus a noninferential belief in the existence of corresponding material objects which cause the sensations, such a belief being liable—but not committed—to error; the function of sensation is to "suggest" the material objects. Thus Reid attempted to retain what seemed the common-sense elements in Locke's account, without the ideas and inferences from them which appeared both unjustified and fatal to it. As on many other topics, Reid's account of perception is tantalizingly incomplete and, without further explication of the notion of "suggestion," appears liable to criticisms similar to those which he had brought against Locke.

Reid rejected the orthodox representationalist theory of memory on similar grounds. In the first place, he denied the existence of the images which the theory held to be likenesses of the event or situation remembered; in effect he was protesting against being misled by the use of the noun "image" into the supposition that there was a special kind of mental entity of which it was the name. Secondly, the supposition that remembering consists of having images, related in a certain way to their originals, would preclude us from any justification of our memory beliefs. An acceptable theory of memory must be such as would entitle us (1) to claim that at least some remembering is reliable (although not infallible); and (2) to provide criteria for distinguishing correct remembering from misremembering or imagining. In general Reid was objecting, although not with entire clarity or consistency, against the "picture" model which seemed the fatal error of the theory of ideas. While all thought requires an object of thought, this does not necessitate that the object shall exist, even mentally. At times, indeed, Reid advances to a view more in accord with 20th-century thought: namely, that a concept is the meaning of the appropriate word or expression, that to have a concept is to know the meaning of the expression (*e.g.*, to have a concept of circle is to know the meaning of the word "circle") and that to know the meaning of a word, expression, or sentence is to know how they are used.

As the founder of the philosophy named after it, Reid may appear to say disappointingly little about common sense directly, but his practice makes his principles reasonably clear. He was claiming, not that common sense is an oracle of truth (this was the view which Kant contemptuously but ignorantly attributed to him), but that there is such a thing as common-sense knowledge, as evidenced partly by the structure of language (which he held, without producing any evidence for it, to be to a high degree uniform from one natural language to another) and partly by the uniformity of our practical conduct.

The business of philosophy is not to challenge what each of us knows perfectly well to be true: for example, that there are material objects of whose existence and character we are aware by perception; that each of us is a continuing and identical person at least as far back as he can remember; that there are other persons like ourselves possessing life and intelligence; that there is some freedom of decision and of action; that expectation of the future based on experience of the past may be reasonable; and so on. To question such pieces of knowledge as these, as though they were empirical hypotheses to be tested, is to misconceive the philosopher's task, which is rather to attempt to understand more fully and clearly than is required for the unreflective, practical purposes of life the meanings of the propositions concerned. If philosophers had paid more attention to the basic facts and functions of language, they would have avoided the extravagances of skepticism and irrationalism into which they plunged. In emphasizing that the typical philosophical problem is not whether we know that something is the case, but what exactly it is that we do know when we know that something is the case, Reid was pointing the way which much British philosophy followed in the 20th century under the more immediate and more stimulating influence of Ludwig Wittgenstein and of G. E. Moore. *See* also KNOWLEDGE, THEORY OF.

McCosh, *Scottish Philosophy* (1875); O. M. Jones, *Empiricism and Intuitionism in Reid's Common Sense Philosophy* (1927). (A. D. W.)

REID, THOMAS MAYNE (later known as MAYNE REID) (1818–1883), Irish-born writer of adventure stories whose works had an important influence on juvenile fiction, was born at Ballyroney, County Down, on April 4, 1818. The son of a Presbyterian minister, he began to train for the ministry, but in 1839 sailed for New Orleans. A varied career as storekeeper, schoolmaster, actor, and trapper and trader among the Indians along the Missouri and Platte rivers provided material for the books which made him famous. In 1842 he settled as a journalist in Philadelphia where he met Edgar Allan Poe (*q.v.*), whom he later defended against the unjust accusations of his biographer, R. W. Griswold. In 1846 he volunteered to fight in the Mexican War, and on Sept. 13, 1847, sustained a severe thigh wound, which never properly healed, when leading the attack on Chapultepec castle. He was believed dead, but after some months in a hospital returned to the United States, resigned his commission, and, in 1849, sailed for Europe with a legion formed to aid the Hungarian revolutionaries, but arrived after their defeat. With *The Rifle Rangers* (1850) he began a long series of adventure stories, the best of which (including *The Scalp Hunters,* 1851; *The Boy Hunters,* 1852; *The Quadroon,* 1856) draw on his own experience. Intended to provide "pleasure and instruction," they combine vigorous action with vivid descriptions of the flora, fauna, and landscape of foreign countries. *The Child Wife* (1868) tells his own love story: in 1853 he fell in love with a 13-year-old girl and married her two years later.

After an attempt (1866) to launch a 1*d.* London evening paper, Mayne Reid returned to the United States, where he founded a boy's magazine, *Onward.* He became a U.S. citizen in 1868 but, after a severe illness, in 1870 returned to England and took up farming. He died in London on Oct. 22, 1883.

See Elizabeth Reid and Charles H. Coe, *Captain Mayne Reid* (1900). (W. L. G. JA.)

REID, WHITELAW (1837–1912), U.S. journalist and diplomat, ambassador to Great Britain prior to World War I, was born near Xenia, O., on Oct. 27, 1837. He graduated from Miami University, Oxford, O., in 1856, and spoke frequently in behalf of John C. Frémont, the Republican candidate for the presidency in that year. In 1860 he became legislative correspondent at Columbus for several Ohio newspapers, including the *Cincinnati Gazette,* of which he was made city editor in 1861. He was war correspondent for the *Gazette* in 1861–62, serving also as volunteer aide-de-camp to Gen. Thomas A. Morris and to Gen. William S. Rosecrans in West Virginia, and was Washington correspondent of the *Gazette* in 1862–68. In 1868 he became a leading editorial writer for the *New York Tribune,* in the following year was made managing editor, and in 1872, upon the death of Horace Greeley, became the principal proprietor and editor in chief. In 1905 Reid relinquished his active editorship of the *Tribune,* but retained financial control. He served as minister to France in 1889–92, and in 1892 was the unsuccessful Republican candidate for vice-president on the ticket with Benjamin Harrison. In 1897 he was special ambassador of the United States on the occasion of Queen Victoria's jubilee; in 1902, special ambassador of the United States at the coronation of King Edward VII; and in 1905 he became ambassador to Great Britain. He died in London on Dec. 15, 1912.

His publications include *After the War* (1867); *Our New Duties* (1899); *Later Aspects of Our New Duties* (1899); *Problems of Expansion* (1900); *The Greatest Fact in Modern History* (1906); and, posthumously, *American and English Studies* (1913).

See Royal Cortissoz, *The Life of Whitelaw Reid* (1921).

REIGATE, a municipal borough (1863) of Surrey, Eng., lies 22 mi. (35 km.) SSW of London Bridge by road. The borough, largely residential, which was considerably extended in 1933, includes the town of Redhill, the village of Merstham, part of which is now a council housing estate, and the parish of Gatton. Pop.

(1961) 53,751. Cherchefelle was the Saxon village mentioned in Domesday Book, but by 1170 its name had been changed to Reigate. The town lies at the foot of the North Downs and there are remains of a Norman castle, which was a stronghold of the Warennes in the 12th–14th centuries and was destroyed *c.* 1648. The castle grounds (5 ac.) are laid out as a public garden. The manor of Cherchefelle was granted by William Rufus to William de Warenne, through whose family it passed in 1347 to the earls of Arundel. It was held by the Somers family from 1697 until 1922, when it was conveyed to the corporation by deed of gift. Reigate Priory, an Augustinian foundation, was rebuilt in 1779 and was purchased by the corporation and Surrey County Council in 1948. The old town hall (*c.* 1728, presented to the corporation in 1922) is on the site of an ancient chapel dedicated to St. Thomas Becket. In a vault below the chancel of the parish church of St. Mary Magdalene (Transitional Norman to Perpendicular) is buried Lord Howard of Effingham, who commanded the English Navy against the Spanish Armada. The Cranston Library, on the upper floor of the old vestry, was founded in 1701. The boys' grammar school was founded in 1675, but the Girls' County Grammar School is a modern foundation (1905). There are a technical college and a school of art. The artist John Linnell lived on Redstone Hill and his son-in-law Samuel Palmer, the landscape painter, died in Redhill.

REIMARUS, HERMANN SAMUEL (1694–1768), German philosopher and man of letters, a notable deist of the Enlightenment, was born in Hamburg on Dec. 22, 1694. He studied at Jena (1714) and lectured at Wittenberg and at Weimar before becoming, in 1727, professor of Hebrew and Oriental languages at the Hamburg *Gymnasium.* Married in 1728 to Johanne Friederike Fabricius, he made his own house a centre of culture and helped to found a public meetingplace for learned and artistic societies.

Reimarus used materials collected by his father-in-law, J. A. Fabricius (*q.v.*), to produce a valuable edition of Dio Cassius (1750–52). In his first noteworthy philosophical publication, *Abhandlungen von den vornehmsten Wahrheiten der natürlichen Religion* ("Treatises on the Principal Truths of Natural Religion"; 1754), he divided the essential problems into three parts—cosmological, biological-psychological, and theological—which, when related to each other, formed a unified deistic system. His *Vernunftlehre* . . . ("Doctrine of Reason"; 1756) was followed by the first version of his *Allgemeine Betrachtungen über die Triebe der Thiere* ("General Considerations on the Instincts of Animals"; 1760), which he was revising till his death: his attempt to define the unique characteristics of animal life yielded a rather complex animal psychology.

Reimarus died in Hamburg on March 1, 1768, having withheld from publication his major work, *Apologie oder Schutzschrift für die vernünftigen Verehrer Gottes* ("Apologia or Defense for the Rational Reverers of God"). G. E. Lessing (*q.v.*) aroused vehement controversy by printing fragments of this work (under the title *Wolfenbütteler Fragmente*) in his *Zur Geschichte und Litteratur,* parts iii and iv (1774 and 1777); Andreas Riem, under the pseudonym C. A. E. Schmidt, published other passages in 1787; D. W. Klose some others in 1850–52; and D. F. Strauss (*q.v.*) described the contents of the manuscript in his *H. S. Reimarus und seine Schutzschrift* . . . (1862; second edition 1877; Eng. trans., *Fragments from Reimarus,* 1879). The standpoint is that of pure naturalistic deism. Miracles and mysteries, with the exception of the Creation, are denied, and natural religion is advanced as the absolute contradiction of revealed religion: discoverable by reason, the essential truths of natural religion, namely the existence of a wise and good Creator and the immortality of the soul, can be the basis of a universal religion, whereas no revealed religion can ever be intelligible or credible to all. The fragment "Von dem Zwecke Jesu und seiner Jünger" ("On the Aim of Jesus and his Pupils") influenced some 19th-century critics.

REIMS (RHEIMS), a city of northeastern France, lies 95 mi. (152 km.) ENE of Paris by road, in the *département* of Marne. Pop. (1962) 138,576. Reims is situated on the right bank of the Vesle River, a tributary of the Aisne, where its valley is reached by the junction canal that connects the Aisne and Marne rivers. It lies on the western margin of the chalk plain of Champagne and is overlooked from the southwest by the Montagne de Reims, the highest part of the Tertiary limestone escarpment of the Île de France. On its lower slopes, and farther south to beyond the Marne valley, are the vineyards that provide grapes for the Champagne wine industry, of which Reims and Épernay are the chief centres. The wine is prepared in vast caves.

Situated at the intersection of the main route leading north from the Rhône valley to the Low Countries with that from the Channel ports to the Rhine, Reims (Durocortorum) was the chief node of the Roman road system in northern Gaul, a much more important route focus then than Paris. It early became a centre of ecclesiastical organization and, from the 3rd century, of an archbishopric. According to tradition, the Frankish king Clovis was baptized by St. Remi (Remigius), archbishop of Reims, and from this event derived the later prerogative of archbishops to consecrate successive kings of France in Reims Cathedral. With few exceptions French monarchs from Philip Augustus to Charles X were consecrated there. The most famous of these ceremonies was that in 1429 when Charles VII was crowned in the presence of Joan of Arc.

From the advantages of its situation the great fairs of Reims developed in the 12th century, and the town received a communal charter in 1139. The woolen industry flourished in the Middle Ages, and was stimulated in the 17th century by Jean Baptiste Colbert, a native of the city, who is commemorated by a statue in the Place de Colbert. The textile industry is now represented especially by the manufacture of flannels. Engineering, glassmaking, and biscuit manufacture are also important. The city is a major junction of modern roads and railways, and its port on the Aisne-Marne Canal handles considerable traffic.

The cathedral of Notre Dame, built in the 13th century to replace an earlier building that had been burned, was one of France's greatest Gothic edifices, with an especially impressive facade. It was destroyed by German shelling in World War I, but was completely restored by 1938 and escaped damage in World War II. Reims was occupied briefly by the Germans in their offensive in September 1914, and after evacuating the city they held the surrounding heights, from which they subjected the city to intermittent bombardment during the next four years, and nearly all its buildings were destroyed. The two Romanesque towers and early Gothic facade of the church of St. Remi (11th–15th centuries) survived, however, as did the Roman triumphal arch, the Porte Mars. The Fine Arts Museum, which houses a notable collection of tapestries and paintings, occupies the buildings of an 18th-century abbey.

REINCARNATION: *see* METEMPSYCHOSIS.

REINDEER, the name for Arctic and subarctic deer of the genus *Rangifer,* which in some parts of the northern polar lands are domesticated. Some authorities regard them as constituting a single species, *R. tarandus,* with several subspecies; others assign them to several separate species. Those native to North America are known as caribou. Reindeer were found until recently from Spitsbergen Island and Scandinavia through Finland and northern Russia to eastern Siberia. In North America two types may be distinguished on the basis of geography and habitat: the northern, or barren ground, caribou inhabit the tundra and taiga; the woodland caribou, the forest regions from Labrador and New-

CHARLES J. OTT FROM THE NATIONAL AUDUBON SOCIETY

BARREN GROUND CARIBOU BULL (RANGIFER TARANDUS)

foundland to British Columbia, formerly penetrating as far south as Maine.

Reindeer differ from all other living deer in that both sexes have antlers; those of the females are smaller and simpler than those of males. The antlers themselves are peculiar in that the brow tine of one side is directed downward over the middle of the face and is often palmated vertically. Reindeer vary greatly in size from the small domesticated races, about the size of a donkey, to much larger races of caribou. They are stockily built animals with large lateral hooves that allow the feet to spread on boggy ground or on snow. Their colour varies greatly, but in general is grayish or brownish, with lighter underparts; the coat is thick and consists of hard, brittle outer hairs covering a dense underfur.

Reindeer are strong swimmers, are always found in herds, and are famous for their seasonal migrations between summer and winter ranges. Their numbers are now greatly reduced. A single calf is usually born after a gestation of 7½ months, but twins are not rare. The staple winter food is a lichen (*Cladonia*), popularly called reindeer moss, which the animals reach by scraping the snow away with the feet (not with the forwardly pointing brow tine as is often thought). In summer the diet also includes grasses and saplings. The main enemies of reindeer are man, wolf, lynx, and wolverine. The reindeer of the Lapps is kept as a beast of draft and burden, as stock for its meat and milk, and for its hide, used for tents, boots, and clothing. *See* also DEER, and references under "Reindeer" in the Index. (L. H. M.)

REINDEER LAKE, in northern Canada, straddles the Saskatchewan-Manitoba border in Precambrian rock terrain near the northern limit of the coniferous forest. At an altitude of 1,150 ft. (351 m.), it is 2,467 sq.mi. (6,390 sq.km.) in area, 152 mi. (245 km.) long and up to 35 mi. (56 km.) wide, irregularly shaped and island-dotted. Fed by numerous streams, it drains southward over a control dam into the Churchill River via the Reindeer. In fur trade days the lake was a transport link and two small settlements formed near its extremities. More recently, commercial and sport fishing produced a third settlement on the east shore connected by road with Lynn Lake. Man. (C. S. BR.)

REINECKE, KARL HEINRICH CARSTEN (1824–1910), German composer, pianist, and conductor who was regarded as the best interpreter of the piano music of Mozart of his time, was born at Altona, June 23, 1824. He appeared in public as a child, toured Scandinavia at the age of 18, and in 1843 settled in Leipzig, where his close contact with Mendelssohn and Schumann was of decisive influence in his development. He conducted the Leipzig Gewandhaus concerts from 1860 to 1895. Of his numerous works, which include operas, symphonies, concertos, overtures, and chamber music, those written for educational purposes are the most valuable and his pieces for children are still fresh. He died at Leipzig, March 10, 1910. (H. GA.)

REINFORCED CONCRETE: *see* CONCRETE.

REINHARDT, MAX (1873–1943), Austrian theatrical producer and director, the most influential and productive theatre figure of his generation, directed many kinds of plays in many types of theatres and introduced new concepts of design and production to audiences in Berlin, Vienna, London, and New York. He was born at Baden, near Vienna, on Sept. 9, 1873. From 1893 to 1903 he studied acting, chiefly under the German director and experimenter Otto Brahm, but spent the rest of his career as a play director and teacher, principally in Berlin.

Reinhardt's famous productions included those at the Salzburg Festival (*see* SALZBURG); *Oedipus Rex* (Vienna, 1910); *A Midsummer Night's Dream* (various stagings, notably Berlin, 1905, and Oxford, 1933); and *The Miracle* (London, 1911). (*See* also THEATRE: *20th Century: Germany;* ACTING, DIRECTION AND PRODUCTION: *Direction.*) He brought together young artists who successfully realized in their costume and scenic designs many of the revolutionary ideas of Edward Gordon Craig and Aleksandr Tairov. He broke the convention of the proscenium wall and staged his plays in circuses, cathedrals, Greek-style theatres, and on cathedral steps. In addition to his spectacles for large audiences, he staged light operas and modern plays in ballrooms (the Redoutensaal in Vienna) and intimate theatres and cabarets.

THE BETTMANN ARCHIVE, INC.

MAX REINHARDT

From the time of his first popular success with *Sumurun,* an Oriental pantomime, to his last spectacle, *The Eternal Road* in New York in 1937, Reinhardt worked on the development of his artistic theories. Chief among his beliefs was that the function of the director was to realize the specific atmosphere of a play and that every play, whether new or old, must be made to live for a contemporary audience. Occasionally his zeal for theatrical effect and publicity caused him to distort the fundamental dramatic values in a script, but those cases are exceptions and insignificant in relation to his total record. He believed in careful preparation of a production before beginning rehearsals, and his director's manuscript or *Regiebuch* for any play, with its detailed annotations and diagrams, is a legendary document.

Reinhardt left Germany in 1933. In Hollywood he directed films and established a school for actors and directors. He became a U.S. citizen in 1940 and died in New York on Oct. 31, 1943.

REINKENS, JOSEPH HUBERT (1821–1896), the first German Old Catholic bishop, was born at Burtscheid near Aachen on March 1, 1821. He was professor of church history at Breslau and became rector of that university in 1866. At the first Vatican Council (1870) Reinkens refused to support the doctrine of papal infallibility and was excommunicated in 1872. (*See* VATICAN COUNCILS.) He attended the first Old Catholic congress at Munich (1871), was elected the first German Old Catholic bishop, and was consecrated at Rotterdam (1873) by Hermann Heykamp, bishop of Deventer, the only survivor of the old Dutch Jansenist hierarchy independent of Rome since 1724. Reinkens took a leading part in the Bonn Reunion Conferences with Eastern Orthodox, Anglican, and Lutheran theologians (1874–75). In 1876 he consecrated Eduard Herzog bishop for Switzerland. In 1889 Reinkens and Herzog, with three Dutch Jansenist bishops, issued the Declaration of Utrecht, which repudiated the innovations of the Council of Trent and is still the Old Catholic doctrinal basis. Reinkens died at Bonn on Jan. 4, 1896. *See* also OLD CATHOLICS.

See Reinkens' *Life* by his nephew, J. M. Reinkens (1906); C. B. Moss, *The Old Catholic Movement* (1948). (C. B. Mo.)

REINMAR VON HAGENAU (REINMAR DER ALTE) (d. *c.* 1205), was the most notable exponent of *Minnesang* toward the end of the 12th century (*see* MINNESINGER). His birthplace was probably in Alsace but he moved early to Vienna where he became court poet of the Babenberg dukes. Among his pupils was Walther von der Vogelweide (*q.v.*), who later became his rival. Reinmar was considered by his contemporaries to be the "nightingale" of the poets of his day. In matters of form he sought purity of rhyme and smoothness of rhythm and rejected any phrase or emotion which might have offended courtly susceptibilities. The modern reader, however, may find his songs stereotyped as he sang mostly of unrequited love. The volume of songs attributed to him is considerable but modern scholarship doubts the authenticity of all but about 30 of them, assigning the rest to his pupils.

See K. von Kraus (ed.), *Des Minnesangs Frühling* (1939). (W. W. Cs.)

REISKE, JOHANN JAKOB (1716–1774), German philologist, who surpassed all his predecessors in the range and quality of his knowledge of Arabic literature, was born on Dec. 25, 1716, at Zörbig in electoral Saxony. From the orphanage at Halle he passed in 1733 to the University of Leipzig, and there spent five years. He bought Arabic books, and when he had read all that was then printed he thirsted for manuscripts. He qualified as a doctor, but failed to secure any medical practice at Leipzig, and

lived, as before, on ill-paid literary hack work. Although the electoral prince gave him the title of professor he was not permitted to lecture. At length in 1758 the magistrates of Leipzig rescued him from poverty by giving him the rectorate of St. Nicolai, and, though he still met with hostility in the university, he enjoyed the esteem of Frederick the Great, of Lessing, Carsten Niebuhr, and many foreign scholars. Reiske died on Aug. 14, 1774, and his manuscript remains are now in the Copenhagen library.

In the *Adnotationes historicae* to his *Abulfeda Annales Moslemici,* five volumes (1789–91), Reiske collected a veritable treasure of original research; he knew the Byzantine writers as thoroughly as the Arabic authors, and was alike at home in modern works of travel in all languages and in ancient and medieval authorities. In Greek his corrections are often hasty and false, but a surprisingly large proportion of them have since received confirmation from manuscripts. He was interested too in numismatics, and his letters on Arabic coinage form the basis of that branch of study.

REITH, JOHN CHARLES WALSHAM REITH, 1ST BARON, OF STONEHAVEN (1889–), one of the principal British architects of the modern pattern of publicly owned but independent utility corporations, was born at Stonehaven, Kincardineshire, Scot., on July 20, 1889. He was educated at Glasgow academy, Gresham's school, Holt, Norfolk, and the Royal Technical college, Glasgow. Trained as a civil engineer, in 1916–17 he was engaged in the United States on the supply of munitions to the United Kingdom. As general manager of the British Broadcasting company from 1922, and director general of the corporation, as it became, from 1927 to 1938, he was responsible for the creation and development of broadcasting throughout the British Isles, and also for the inauguration of the empire short-wave broadcasting service and the first regular service of high-definition television in the world (1936). He had been knighted in 1927. In 1938 he became chairman of Imperial Airways and in the following year was responsible for its merger with British Airways and the creation of the British Overseas Airways corporation, of which he became chairman. He was made a peer in 1940. After holding a number of ministerial and other appointments in World War II, Lord Reith was responsible in 1946 for a reordering of the cable and wireless system of the commonwealth, becoming chairman of the new Commonwealth Telecommunications board (1946–50). He was chairman of the New Towns committee (1946), the Hemel Hempstead Development corporation (1947–50) and the National Film Finance corporation (1948–51). From 1950–59 he was chairman of the Colonial Development corporation and served on other commercial and industrial boards. Lord Reith published his autobiography, *Into the Wind,* in 1949. (G. R. M. G.)

REJUVENATION, or the restoration of youthfulness, has long been an aspiration of mankind. To stop the inevitable march toward senile decline, to turn the clock back, countless generations of men from philosophers to explorers have sought the elixir of life, the source of eternal youth. Although the causes of aging have been little understood, a most obvious change occurs in the reproductive capacities of men and animals as they approach the twilight of their mature years. It is not unnatural, therefore, that the genital powers and the genital organs have been the centre of preoccupation by those who have sought the secret of rejuvenation.

Early historical records indicate that the elders and priests of ancient China and India, 3,000 years ago, consumed the sexual organs of wild animals in order to improve their vigour and acuity and thus to offset the decline of old age. Long before the Christian era, roughly 1400 B.C., the testicles of sacrificial animals were employed to counteract sexual weakness. Such fancy and such practices have not waned during the intervening centuries, since some primitive societies still indulge in these crude attempts at rejuvenation.

The achievement of rejuvenation was claimed during the early 20th century by several surgeons of Europe and the U.S. who maintained that operations on the genital organs or transplantation of young testicular tissue into elderly men brought about a new feeling of well-being, physiological youthfulness and, in some instances, a renewal of sexual potency. This era stemmed from the accounts of the physiologist Charles Edouard Brown-Séquard (*q.v.*) who in 1889, at the age of 70, injected himself with testicular material from dogs and guinea pigs and claimed a renewal of vigour, mental alertness and the "enjoyment of life." Twenty-five years later Jürgen W. Harms believed that he had accomplished the same thing in senile guinea pigs and, further, that he had regenerated sexual activity by the transplantation of testicles from young, healthy animals.

The foremost names in the field of induced rejuvenation were those of the Viennese scientist Eugen Steinach who experimented mostly with rats, and Serge Voronoff, a French surgeon who combined animal and human experimentation. The Steinach operation consisted merely of ligation and severance of the male seminal duct. Voronoff transplanted young human or monkey testicular tissue into the testicular sacs of elderly men. In both procedures, the operation was regarded as increasing the secretion of the masculinizing hormones (androgens) by the testes, thereby giving new vigour to the organism (*see* HORMONES). In the most dramatic cases of rejuvenation of 65- to 83-year-old men, the results claimed were long-lasting improvement in mental alertness, sense of well-being, visual acuity, muscle tone, blood pressure, hair growth, skin elasticity, libido and sexual potency.

Although loudly proclaimed, these procedures were not well founded in theory and have not withstood the tests of time and confirmation. No evidence has been discovered that aging of the body as a whole is dependent on either the activity or the failure of the sexual glands per se. These glands have their own characteristic functional life span, just as do other organs and tissues in the organism. Both the spermatozoa-forming and the hormone-secreting functions of the testes are mainly devoted to reproduction of the species and not to growth, differentiation and maintenance of the body against the ravages of old age.

Voronoff's transplantations of monkey glands in men could not possibly have persisted as active, growing tissues and could at best only have supplied a temporary exogenous source of androgenic substance. The apparent results were probably mainly responses to the sudden and temporary flood of androgen throughout the system, combined with readjustment in subjective and psychological attitudes, and improvement in nutritive and constitutional factors. It has been well recognized among clinical circles that some cases of human infertility in both men and women have responded to improved conditions of diet, rest, relaxation and peace of mind when previous medical therapy had been of no avail.

With the chemical identification and synthesis of the male hormone testosterone there was ample opportunity to test its capacity to induce true rejuvenation as well as to study its general physiological effects on the organism. Its administration to elderly men followed in some instances by feelings of well-being, sexual interest, improved circulation and increased muscle tone, but analogous results also have been obtained with other stimulants and strengthening methods. The effects are temporary and did not offset the slow decline of old age. Indeed, some danger is involved in such a one-sided stimulation since the organism as a whole may not be physically constituted to withstand the sudden and abnormal stress.

The systemic effects of testosterone administered to experimental animals under controlled conditions were found to include a multitude of physiological responses: modification in blood pressure, red blood cell count, muscle tone, glycogen storage, electrolyte and water retention, enzyme activity, carbohydrate and protein metabolism, oxygen and carbon dioxide exchange and brain wave pattern. Moreover, it is known that through the intricate integration of the endocrine system androgen administration has an important action on the all-powerful pituitary gland and on the adrenals as well. Obviously then, a sudden change of disturbance in the androgen balance might have profound effects throughout the system. A practical example of the effect of androgen stimulation may be found in the annals of horse racing: a run-down and over-aged horse was able, after testosterone administration, to perform well with his younger competitors. The response was

temporary, however, and not devoid of some risk.

Attempts to induce the revitalization by surgical means have been confined to the male. Apparent rejuvenation, however, has been frequently described in women suffering from ovarian tumours and reproductive disorders. Misuse of the term in these instances has resulted from the effects of excessive secretion of the feminizing hormones (estrogens). Although estrogens may seem to offset some of the appearances of aging—hence their incorporation into facial creams—the rejuvenative effects are relatively superficial. As in the male, the sexual hormones may alter the background of physiological reactions and modify the structural integrity of the cells and tissues, but they have little lasting effect on the primary causes of aging and senility.

"Rejuvenescence" is the biologist's term for certain processes undergone by protozoa (single-celled animals) such as *Paramecium.* (For these processes, called conjugation and endomixis, *see* REPRODUCTION.) Rejuvenescence, however, is analogous in the higher animals not to rejuvenation of the individual but to procreation of a new being. In man and all other creatures, life continues uninterruptedly from generation to generation through the germ plasm, the source of posterity. Thus, while the germinal elements may be considered immortal, the body seems predestined to grow old and die, and no means have been found to seriously alter this decline.

RELAPSING FEVER (FEBRIS RECURRENS) is an infectious disease characterized by recurring febrile symptoms and caused by spirochetes that have been given a number of conflicting genus and species designations: *Borrelia* (*Treponema*) *recurrentis* (*obermeieri, duttoni,* etc.). The spirochetes are transmitted from man to man by lice of the genus *Pediculus,* and from animals to man by ticks of the genus *Ornithodoros.* The human disease is characterized by sudden onset with violent febrile symptoms, which persist for about a week in cases contracted from lice, and usually for a shorter period in the tick-transmitted disease. The attack ends by crisis with profuse sweating, followed after about a week, during which time the patient is fairly well, by a return of the febrile symptoms. Additional relapses may follow—rarely more than one or two in the louse-borne disease, but up to 12 (usually decreasing in severity) in cases contracted from ticks. The mortality is variable, ranging from nil in some tick-transmitted varieties to 6% or as high as 30% in some recorded louse-borne epidemics associated with famine conditions. The spirochetes may invade the central nervous system and cause a variety of neurological symptoms, although these usually are not severe.

Relapsing fever spirochetes were the first microscopic organisms to be associated clearly with serious human disease. Otto Obermeier observed these organisms in the blood of relapsing fever patients in 1867–68 and published his observations in 1873. The organisms are corkscrew-shaped spiral threads, which rotate rapidly in performing forward, backward, and twisting movements.

They are easily observed in dark-field microscopic preparations of the patient's blood collected during the height of a febrile attack, but disappear from the blood during the intervals between attacks. These observations, as well as the relapsing symptoms, have been related to changes in the immunological (antigenic) characteristics of the spirochetes, which cause each attack and relapse. As the patient develops immunity to the prevailing immunological type and recovers from the attack, a new (mutant) immunological type of the spirochete develops and produces the relapse. Louse-borne relapsing fever has tended to occur in extensive epidemic outbreaks when human populations live under conditions which are conducive to louse infestation. Since neither the bite nor the excreta of the louse is infectious, human infections usually result from crushing the louse on the skin while scratching. Tick-transmitted relapsing fever does not occur in extensive epidemics. Cases usually are related to tick-infested human or animal habitats, because the ticks tend to engorge rapidly, detach, and hide about the premises while digesting their meal, mating, and laying eggs. The adult ticks may live and remain infectious for as long as five years without feeding. The spirochetes frequently invade the eggs of infected female ticks and survive in the body of the developing larvae and nymphs. Therefore, all developmental stages of the tick may transmit the infection by bite or otherwise.

Arsphenamine and related arsenical drugs have been used extensively in the treatment of relapsing fever. However, many treatment failures with these drugs have been recorded. Penicillin has proved effective in curing many cases of the disease. Other antibiotics such as aureomycin, terramycin, and related compounds also have proved to be effective therapeutic agents. Inadequate therapy commonly results in relapse after treatment, probably due to the persistence of live spirochetes in the brain, where the drug concentration does not reach curative levels. After treatment these protected spirochetes may reinvade the bloodstream and start a relapse. (V. T. S.)

RELATIVITY. Since the time of Galileo the concept of relativity, in its broadest sense, has always been present in physics. Loosely speaking, this concept can be expressed simply as a question: Do the laws of nature, and hence the physical situations described by them, always appear to be the same to different observers, even though the state of motion of the observers is not identical? It is with this question that the following discussion is concerned.

GALILEAN RELATIVITY

If we wish to describe a physical event, a system of reference is needed to specify its position. The reference system can be formed by a coordinate system in space and by clocks that are fixed to this coordinate system to indicate the time. Also, a noncommittal word is needed to describe experience. Consider the experiences as a succession of events, each of which happens at a given point in space at a given time. Mechanical experimentation has shown that there are systems of reference such that a body in them, not acted upon by external forces, moves with constant speed along a straight line, and the laws of mechanics take a very simple form; to wit, if forces are acting upon the body, the acceleration will be proportional to the acting force. Such frames of reference are called inertial. (The name originates from the way the laws were visualized. It may be assumed that an innate property, inertia, keeps the body moving on a straight line in the absence of external forces, while the acceleration arises via an interplay of the external forces and inertia.) Is there more than one inertial frame? If so, then all these inertial frames will be equivalent, since in all of them the laws of mechanics (and, hopefully, the laws of physics as well) will be the same. Make a survey of everyday experiences and it is observed immediately that such equivalent systems of reference do indeed exist. For example, consider the fact that experiments performed upon the earth, involving only observations relative to the earth, reveal nothing about the motion of the earth around the sun, not to mention the motion of the solar system through space. Similarly, observations performed in a smoothly moving railway car, without looking out the window, do not permit the decision that the car is at rest or in uniform motion. Of course, if the car proceeds with jolts it is clear that it is not at rest, or not moving with a constant velocity (*see* MECHANICS).

Thus first tentatively announce this statement: if a system of reference S is inertial, and if another system S′ moves with a constant velocity relative to S, S′ will also be an inertial system of reference. However, this does not permit complete specification of the relations between the description of events in S and S′. To do this requires an answer to the following question: If in S′ an event took place at the point x' at time t', what will be the place x and time t of the same event in system S?

To fix the ideas with an example next consider a simple case. Brown is traveling in a railway train that moves with a uniform velocity of 60 mph along a straight line. This moving train is system S′; the distance x' can be measured, say, by numbering

the cars. The time t' is the time shown on the clocks in each car. While Brown is walking to the dining car, he slips and breaks his leg. This is the event that will be discussed. This event happened in the first car, and x' can be specified by measuring it along the train and tracks. The time when the event happened was just two hours after the train's departure, according to the clocks in the train. This specifies t', to wit $t' = 2$ hr. Now, shifting to another frame of reference, S, the frame in which the railway stations are at rest, what are the values of x and t? Here classical mechanics makes the following assumptions: the time of the event is the same in both frames (the clock at the railway station shows the same time as the clocks in the train); lengths measured in both frames are the same. Consequently, in frame S, $t = t' = 2$ hr. In turn, x can be calculated this way: The train has traveled for two hours, and during each hour the distance covered was 60 mi.; hence, the total distance traveled is 120 mi. If distances in S are measured from the point of departure, $x = 120$ mi. Formally, this relationship between the coordinates x, y, z, t and x', y', z', t' gives the following transformation equations:

$$\begin{aligned} x &= x' + ut' \\ y &= y' \\ z &= z' \\ t &= t' \end{aligned} \tag{1}$$

Here it has been assumed that the coordinate axes in S and S′ are parallel, that their origins coincide, and that the motion takes place in the x direction; u is the velocity of the primed coordinate system S′, relative to the unprimed one S. A transformation based on these assumptions bears the name Galilean transformation.

Thus the principle of special relativity takes the following form in classical mechanics: if S is an inertial system of reference, and S′ is a system of reference that moves with a constant velocity relative to S, then the laws of mechanics must have the same form in S and S′, provided x, y, z, t and x', y', z', t' are connected by a Galilean transformation. Briefly, it is said that the laws of Newtonian mechanics are invariant under Galilean transformations.

Of course, the next question is whether the rest of the physical laws are also invariant under this transformation. In other words, this would mean that such experiments that do not rely exclusively on the laws of mechanics should also fail in telling the observer whether he is at rest or in uniform motion, using the connections given by equations (1) between the primed and unprimed quantities. Such experiments are encountered in electrodynamics where concern is with the behaviour of the electric and magnetic fields; *e.g.*, the propagation of light. However, it is very soon realized that such is not the case. The simplest way to see this is perhaps the following. The Galilean transformations, equations (1), give rise to a certain addition law of velocities, the relation commonly used in everyday life. For example, if a man walks along a moving train with a velocity of 2 mph relative to the train, in the direction of motion of the train, and if the train moves with a velocity of 60 mph along the tracks, then the velocity of the man relative to the tracks will be, it is said, 62 mph. If in place of the walking man there is a light signal traveling through the train, emitted from a source on the train, it would be expected that its velocity also would be different if it is measured relative to the train or relative to the tracks. However, experiments show that the speed of light is the same in all inertial systems of reference. (The early Michelson-Morley experiments will be discussed later.) Consequently, the Galilean principle of relativity applies only to mechanics, and not to electrodynamics. Putting it in another way, the Galilean principle of relativity and the constancy of the light velocity in an inertial frame of reference seem to be empirically incompatible.

SPECIAL THEORY OF RELATIVITY

The resolution of this paradox was accomplished by Albert Einstein in 1905. He clearly realized the three assumptions underlying the Galilean principle of relativity and the different roles the constancy of light velocity plays in each. The three assumptions were the following: there are inertial systems in which the laws of physics are identical; if one system is inertial, any system of reference that moves with a constant velocity relative to the first one is also inertial; the transcription of space and time data from one inertial system to another has to be done according to the Galilean transformations as given by equations (1). The first two assumptions assert that the relative configurations of bodies determine the physical occurrences (not their configurations and motions relative to some external frame of reference), while the last indicates how observers must translate the results they have obtained in one inertial frame to get the results observed in any other inertial frame. Experiments indicate that in electrodynamics, as well as in mechanics, all phenomena depend on relative configurations and motions only. Thus the first two assumptions should be valid no matter what assumptions are made about the velocity of light. What about the third one? As has been seen in the discussion preceding equations (1), the Galilean transformations assume tacitly that the position and time of occurrence of an event are the same in all inertial frames. The question arises whether or not this assumption is sensible if the velocity of propagation of signals (light signals) is not infinite. This would question, then, in the example of the train, whether it is sensible to assume that the clock at the railway station shows the same time as those in the moving train. It can be seen that this is not a valid assumption. To show this, let us try to achieve simultaneous operation of the clocks. We could start two identical clocks, one in the railway station and one in the car when the train is at rest at the railway station. If the rate of the clock would not change when the train is set in motion we would have accomplished our task. However, we do not know this, and we either have to test this hypothesis or proceed in a different fashion. What we inevitably will do is the following: we take two identical clocks, put one on the train and leave the other one at the railway station. Now, when the train is in motion we send a signal from the station to the train, say exactly at noon. If this signal would travel with an infinite speed we simply would set the clock in the train to indicate noon, and the synchronization would be accomplished. However, if the signal travels with a finite speed we must take into account the time that is needed for the signal to reach the train. It is just this delay that is ambiguous. The conductor, knowing that the stationmaster is to send the signal at the time t later than the train was at the station, says that the distance is ut, where u is the velocity of the train, and if the signal velocity is c, the delay is $(u/c)t = \beta t$, where $\beta = u/c$. He will then expect to receive the signal at $t' = t\ (1 + \beta)$. The stationmaster will say that, since the train is receding during the signal's flight, the distance traveled by the signal is $u(t + \Delta t)$ and the delay time is given by $\Delta t = \beta(t + \Delta t)$ or $t' = t + \Delta t = t(1 - \beta)^{-1}$.

It will not do to let the conductor correct for his own motion, since this effectively puts him in the stationmaster's frame of reference and then there is no comparison made between clocks set up in different frames. Each must take the point of view that he is at rest and the other one is receding from him. Otherwise, one of the frames of reference would be preferred; *e.g.*, if the conductor corrects for his own motion, this would make the stationmaster's frame preferred. The example with trains is poor in the sense that we intuitively consider the stationmaster's frame as if it were at rest and tend to correct the conductor's computation since the former is at rest relative to the earth.

The difference in the two computations is exactly that in the naïve Galilean reference the signal velocity c cannot take the same numerical value in two reference systems moving with a velocity u with respect to each other. Since both conductor and stationmaster observe, in the train and in the station, respectively, that light velocity has the same numerical value c, each computes the delay time as though the other is moving away from him. The conflict between the computations of conductor and stationmaster is resolved if each believes that the other's clock runs slow by the factor $\sqrt{1 - \beta^2} = \sqrt{(1 + \beta)(1 - \beta)}$. The conductor will then say that his clock should register $t' = t(1 + \beta)/\sqrt{1 - \beta^2} = t\sqrt{(1 + \beta)/(1 - \beta)}$, whereas the stationmaster will compute $t' = t(1 - \beta)^{-1}\ \sqrt{1 - \beta^2} = t\sqrt{(1 + \beta)/(1 - \beta)}$. They will still disagree about whose clock runs slow, and still disagree about the delay in the signal, but they will agree in the computation of the

relation between t' and t, an agreement that is verified experimentally.

To sum up this important step, we can say that the constancy of the velocity of light in different frames, and the existence of equivalent frames, are logically compatible if we modify the transcription of space and time data from one inertial system to another. This means that we must find another set of transformations which will take the place of the Galilean transformations. Moreover, this modification is not only permissible but required, from a physical standpoint, since it is the mathematical description of the empirical procedure to set up synchronous clocks in different inertial systems of reference. It was the brilliant achievement of Einstein to realize that this modification of our space and time concepts (to achieve the logical compatibility of equivalent frames with the existence of a constant velocity of light) is required if we analyze carefully how a finite signal velocity influences the meaning of time in a system of reference, if time is defined in terms of operations such as the indications of clocks that are situated in the immediate neighbourhood of the event, moving with the same velocity as the observer.

Our next step is then to find that set of transformations which will replace the Galilean set. This will furnish us with the relations that tell us how to correlate space and time data in two different systems of reference, moving with a constant velocity relative to each other, in such a fashion that the velocity of light should be the same in both. If we try to satisfy this last condition we find the transformations to be of this form:

$$\begin{aligned} x &= (x' + ut')\gamma \\ y &= y' \\ z &= z' \\ t &= (t' + \frac{x'u}{c^2})\gamma \end{aligned} \qquad (2)$$

where c is the speed of light, $\beta = u/c$ and $\gamma = \sqrt{1-\beta^2}$. The relative arrangement of the coordinate systems is the same as for equations (1). These equations describe the so-called Lorentz transformations, named for Hendrik Antoon Lorentz, a Dutch physicist who investigated them for the first time before Einstein.

We have then a framework which is based on three postulates: that inertial systems of reference exist; that inertial systems differ from each other at most by the fact that they may move with a constant velocity relative to each other; and that the transcription of space and time data from one inertial system to another is done according to the Lorentz transformations, equations (2). The physical description of the external world which satisfies these conditions is called Lorentz invariant and forms the Special Theory of Relativity.

The experimental confirmation of this theory is so extensive that we can give only a few examples. First let us discuss the special implications of the Lorentz transformations. Naturally, we will expect that some interesting consequences arise from the fact that we no longer have an absolute time, the same in all frames of reference. This means that both the spatial distance between points and the duration of a process will change as we change systems of reference. For example, a metre rod, if at rest relative to us, has the length one metre. Set it in motion in the direction of its axis, measure its length again, and the new measurement will be less by a factor $\sqrt{1-\beta^2}$. For ordinary velocities this factor is practically one; for large velocities, however, it may be much less than one. For example, if the metre rod is flying by an observer with a velocity of about 0.85 times the velocity of light ($\beta = 0.85$), the observer will measure its length to be only a half metre.

With time indications it is just the other way around. The seconds indicated by a moving clock will be longer by a fraction $1/\sqrt{1-\beta^2}$ (longer, since this factor is larger than one). This is very dramatically confirmed by modern experiments on elementary particles. In nature we encounter elementary particles, μ mesons, which have a rather short lifetime. In principle this lifetime could be used as a time measure, and so the meson could function as a clock. Accordingly, the lifetime of a moving meson ought to be longer than the lifetime of a meson at rest. In cosmic rays the mesons move practically with the velocity of light, and thus the life of a moving meson should be much longer than that of the meson at rest. Indeed, mesons that are stopped in an absorber have a lifetime of about 1.5×10^{-6} sec. On the other hand, in cosmic radiation a meson travels a distance of about 50 km. before it decays. From this fact we find that the speed of such a meson is about $(1 - 1/5{,}000)$ times the velocity of light, and the lifetime of a meson in our reference frame is increased by the enormous factor of 50 (*see* COSMIC RAYS; PARTICLES, ELEMENTARY).

As far as electrodynamical experiments are concerned, they naturally will agree with the Special Theory of Relativity, since the latter was created just to incorporate these experiments. Consequently, the success of Maxwellian electrodynamics means automatically the success of the relativity theory as well. For historical reasons we mention the famous Michelson-Morley experiment that showed convincingly that the velocity of light is the same in all inertial systems of reference. The idea of the experiment, which is due to James Clerk Maxwell, is very simple. Suppose that the velocity of light does depend on the state of motion of the observer; then, test the consequences of this hypothesis. We send out a light signal in the direction of motion of the earth, and another signal in the opposite direction. In one case the observer travels in the same direction as the light, which, under the hypothesis, would make the observed light velocity less than if the observer had been at rest. In the other case the velocity of light as observed should be larger than the velocity observed by an observer at rest. The difference between these two velocities could be observed interferometrically. This task was performed first by A. A. Michelson (1881), and later in improved form by Michelson and E. W. Morley (1887) (*see* MICHELSON-MORLEY EXPERIMENT). The result was negative; no difference in the velocity of light was found. Naturally, there were attempts to explain this before establishment of the Special Theory of Relativity as discussed in ABERRATION (OF LIGHT).

In 1893 G. F. Fitzgerald, an Irish physicist, and in 1895 Lorentz proposed independently the following explanation. Suppose that the velocity of light does vary with the state of motion of the observer. But suppose as well that the linear dimension of a body in the direction of the motion contracts in the ratio $\sqrt{1-u^2/c^2}$. Then, the observed velocity would be the same, independent of the velocity of the observer. Moreover, this supposition conformed with the theory of electrodynamics, since Lorentz showed that if matter consisted only of charged particles held together by electromagnetic forces, then, if set in motion, the relative positions of the particles would adjust themselves in such a fashion that the contraction would take place.

We know now that this contraction does not depend on the special nature of the forces which keep matter together, but is a simple consequence of the Lorentz transformations, as we have seen in the discussion of equations (2).

Let us turn now to the mechanical experiments. First, a remark. While electrodynamics was born Lorentz-invariant, though its creator, Maxwell, did not realize it, mechanics was made to be Lorentz-invariant. This happened in two steps. First, modifications were introduced in the definitions of mechanical quantities so that the Newtonian equations of motion would conform to the Special Theory of Relativity. The classical concepts of mechanics, such as inertia and force, were retained, however. Finally, with the advent of the General Theory of Relativity, even these concepts were modified or removed. In this section we will discuss the first stage of development, while the next stage will form the content of the description of the General Theory.

The reformulation of dynamics in a Lorentz-invariant form, while retaining the classical concept of force, brought some beautiful results. Classical dynamics contained three most important laws concerning the conservation of energy, momentum, and mass. These laws were essentially independent, and we would have been able (in principle) to drop one and retain the others. In the Lorentz-invariant formulation this freedom no longer exists. Here, the three conservation laws are fused into one, and the violation

of one entails the violation of all. Moreover, because the conservation of energy is linked to the conservation of mass, processes are permitted which would change energy into mass, or mass into energy (if the amount of mass which disappears in a given physical event is m, there will appear an amount of energy $E = mc^2$, c being the speed of light). Indeed, the last of these processes is the one which provides us with prodigious amounts of energy in nuclear reactions (*see* ATOMIC ENERGY).

In other respects, the differences between the classical and relativistic dynamics are most pronounced in the description of fast particles. This is natural, for we know that the difference in the classical and relativistic descriptions arises from the fact that in the classical theory there is no limiting velocity. If a particle moves slowly, it cannot make any difference, as far as the result is concerned, whether we consider a limiting velocity which is very large, or actually infinite. Expressing it in another way, classical Newtonian mechanics must be a limiting case of relativistic mechanics. This limiting case can be reached from the relativistic formulation by placing the velocity of light equal to infinity, and it can be applied in cases where the actual velocities of the bodies under description are much less than that of light. (This is a good example of the growth of physical theories. Each theory describes a part of our experiences correctly. However, the conditions under which this description is correct are usually less general than was originally thought. With the arrival of new facts this is realized, and a new, more general theory is created which, though it may be based on entirely different concepts, contains the mathematical formalism of the old one as a limiting case. Thus a new physical theory does not replace the old one but generalizes it.)

There are numerous examples showing that the proper description of fast-moving particles is the relativistic one. In modern research, physicists often experiment with very fast particles, which are accelerated in machines by electromagnetic fields. In the design of these machines (cyclotrons, betatrons, etc.) the physicist uses relativistic dynamics with the same confidence that an engineer feels when he uses Newtonian mechanics to design automobiles. The successful operation of particle-accelerating machines shows how correct the relativistic description of fast particles is (*see* ACCELERATORS, PARTICLE).

The mathematical description of the Special Theory of Relativity and its content was greatly simplified by the geometrical interpretation given to it by Hermann Minkowski, a German mathematician. This interpretation had the most far-reaching significance, since geometrization provided the clues that finally enabled Einstein to generalize the theory so as to embrace gravitational forces as well. Moreover, Minkowski's interpretation suggested the proper mathematical tools, tensor calculus and differential geometry, which gave the theory great elegance.

The underlying idea is the following. Every observer must specify four data (x, y, z, t) to describe an event. The first three of these will specify the location of the event relative to a coordinate system, while the last one specifies the time relative to a clock at rest in this coordinate system. In those cases where there are only three (or two) quantities to be specified, it is quite customary to draw a graph to represent the totality of these measurements at one glance. Even if in practice we cannot draw a four-dimensional graph (plot four quantities at once), we can think about it. To facilitate our understanding we will now contemplate only situations where the position can be given by two data only. So, let us suppose that we are aboard an ocean liner and we want to have a graphical record of our journey. The simplest thing to do is to take the map and at each hour, say, put a point at the proper latitude and longitude where the boat is, and write next to it the time. It is much more revealing, however, if we make a three-dimensional model, and put the dot not on the map, but above the intersection of the proper longitude and latitude. The perpendicular distance from map to point should be proportional to the time elapsed from the departure. If we do this each hour and finally connect all these points with a thin wire, the wire will contain in a graphical form all the information about the journey.

This information shows not only the location of the boat at a given time, but much more. If the wire is straight, it tells us that the boat has traveled on a straight line with constant speed. If the wire lies in one plane (normal to the map), but describes a curve in this plane, the boat was traveling on a straight line, though the speed did change during the course, and so on.

Now if we take a particle instead of the boat and note mentally in a four-dimensional space its position (x, y, z) at time t for each instant of time, we will get a similar plot. Each point on the plot specifies an event, and the resulting curve is called the world line of the particle; it describes the history of this particle. The four-dimensional continuum in which the plotting takes place is called space-time (*q.v.*). The immense importance of this concept is as follows: suppose that several different observers, each using a different inertial system of reference, are observing the motion of a particle, and each is asked to construct a space-time diagram of the motion. According to the Special Theory of Relativity, each observer will construct exactly the same curve in space-time for the history of the particle. The different states of motion of the observers (since they use different inertial systems of reference) will manifest themselves by the fact that the coordinate axes in space-time, x, y, z, t (which localize an event in space-time relative to the inertial system of reference used by the observer), will be different for different observers. The relation between these axes is that given by equations (2); thus, we can pass from one set of axes in space-time to another set by a Lorentz transformation.

This is the great moment of geometrization. In geometry we are dealing with the description of objects and the relations among them. Such objects can be points, lines, planes, surfaces, bodies, etc. We describe them by giving the coordinates of the corresponding points relative to a coordinate system. If we change the coordinate system we change the description, but we do not change the configuration of the points we describe. In relativity theory the histories, the configurations of points describing events, are objective. Their description relative to an observer depends, however, on the coordinate system in space-time that the observer uses and the coordinate system in turn depends on the state of motion of the observer. A Lorentz transformation corresponds to a change of coordinates in space-time. As a coordinate transformation leaves the configuration of points unchanged, so a Lorentz transformation does not change the histories. Also, in a coordinate transformation the new coordinates, in general, will be given combinations of the old coordinates. In a Lorentz transformation the new space-time coordinates will be a combination of the old space-time coordinates. The mixing of space and time coordinates in a Lorentz transformation is then no more mysterious than the mixing of coordinates in an ordinary coordinate transformation. Moreover, the physical laws will now be geometrical propositions concerning world lines. In this way our geometrical intuition can come into play again, and can furnish help in the formulation of theories and problems. We will at once expect that the significant geometrical properties, such as curvature, torsion, and straightness, will also describe physically significant properties. Indeed, this is so. For example, a curved world line shows that the particle was accelerating, and thus we know that a force was acting on the particle whose history is described by this world line. The place and time of the action can be determined by locating the curved section of the world line relative to a system of reference in space-time. The magnitude of the curvature will be simply proportional to the magnitude of the force and the work done by the force. As a corollary we see that if no forces are acting on a particle its history is a straight line in space-time.

In geometry it is the distance between two points which has an intrinsic significance, while the projections of this distance upon the coordinate axes depend on the coordinate system, and vary as the coordinates change. A similar thing happens in relativity theory (*see* GEOMETRY).

The distance between events, which we will call an interval, is something absolute, represented by a line segment connecting the two events. Each observer will split this interval into a

space part and a time part, relative to his own inertial system of reference; the spatial part will be the projection of the interval upon the spatial coordinates (x, y, z), while the time part will be the projection of the interval upon the time axis. This splitting into spatial and time parts will depend on the orientation of the coordinate system x, y, z, t in space-time.

For example, take as one event the Great Fire in London, and for the other event the outburst of the Nova Persei. The observer who is at rest relative to the earth (and so, relative to London) will split space-time with his coordinate axes and find that the outburst took place a century before the Great Fire and many millions of miles away from London. An observer who travels with a constant velocity relative to the earth may conclude that for him the distance and time elapsed is different. There will even be an observer with a certain velocity such that for him the two events took place simultaneously. Each observer slices up space-time into a space part and a time part, and the slicing depends on the orientation of the coordinate system. Thus, as Minkowski put it: "Space in itself and time in itself sink to mere shadows, and only a kind of union of the two retains an independent existence."

GENERAL THEORY OF RELATIVITY

The Special Theory of Relativity has not only solved problems, but has also posed some new questions. As is usual in physical theories, the advent of new viewpoints forces us to reexamine the concepts that we used freely before. With the advent of the Special Theory of Relativity these questions were abundant. In discussing the Special Theory we have learned that the histories in space-time have some permanent significance, at least as far as Lorentz transformations are concerned. Now, if the geometrical interpretation makes sense, we would think that the other, more general transformations should be also of significance. (A geometrical figure remains the same, irrespective of the coordinates we use to describe it.) At first sight the introduction of general transformations is clearly nonsensical. Such transformations in space-time correspond physically to the use of noninertial coordinate systems. Now, it is a familiar story that in noninertial systems of reference we have fictitious forces acting. Such forces are the centrifugal and Coriolis forces, which manifest themselves in rotating systems of reference. They are called fictitious because we can make them disappear by changing back into an inertial frame of reference. Consequently, we can distinguish between these frames of reference and inertial frames, and thus the simple principle of relativity cannot hold. However, our geometrical intuition insists that there must be something behind this idea. So let us analyze what happens if we observe a physical system from an accelerated system of reference. The fictitious forces we encounter have two important characteristics. First, they impart the same acceleration to every body, irrespective of its mass; second, these forces can be transformed away by the simple device of transferring ourselves to an inertial system of reference. As an example, consider what happens when we ride in a railway train. As long as the train moves in a straight line with a uniform velocity, everything inside the train behaves as if the train were at rest. Now the train makes a turn; the luggage in the train starts to slide, the water surface in a pitcher is no longer horizontal. Sitting inside the train, we conclude that a force is acting on these objects. The acceleration imparted by this force is the same for each body, and it disappears as soon as the train runs in a straight line with constant velocity. However, we can also say that, after all, the objects in the train tended to continue to travel on a straight line with a uniform velocity on account of their inertia, and only we, the observers (and our system of reference, the train), were accelerating; hence, it is natural that all objects should have the same acceleration, since after all this is just the observer's acceleration in the opposite direction. Thus, the inertia of the body is essentially what we see as a fictitious force. Also, it is obvious that if we cease to be in an accelerated frame of reference, we will see the other objects travel along straight paths with constant velocities (if they are not acted on by other forces), thereby transforming away the fictitious forces. If we say all that, we are correct. The puzzling thing, however, is that there is another force, the gravitational force, which has these two properties. A falling apple undergoes the same acceleration as a falling cherry, though their masses differ. Also, if we fall together with the apple, it will appear to be at rest relative to us, apparently with no force acting on it (*see* FORCE; GRAVITATION: *Theories of Gravitation*).

This suggests that there must be an equivalence between noninertial systems of reference and gravitational fields, in the sense that an observer performing observations locally cannot distinguish between gravitational forces and forces which arise on account of accelerated systems of reference. Consequently, the admission of noninertial systems is necessary to construct a theory of the gravitational forces. But if accelerated systems are equivalent to gravitational forces, then gravitational forces should be in all respects similar to the fictitious forces. We have seen that these fictitious forces are essentially the manifestations of the inertia of bodies. The gravitational forces then must be similar manifestations. How could we formulate this?

We have learned in the Special Theory that the world lines of particles not acted upon by any forces are straight lines. These world lines have the important geometrical property of being as "straight" as possible. In geometry such lines are called geodesics. This we will consider as the proper characterization of inertia, and we can say that the world line of a particle subjected only to its own inertia is the straightest line in space-time; it is a geodesic. Then, if we exclude any other forces, except gravitational and other fictitious forces which should be the manifestations of the inertia of the bodies, we should be able to say the following: there are no forces acting on bodies; bodies always move freely under the influence of their own inertia. Consequently, their motion is such that their world lines are geodesics in space-time.

This space-time, of course, cannot be the space-time of the Special Theory, for there, we have just learned, the geodesics correspond to the motion of bodies which are not subjected to gravitational forces in the ordinary Newtonian usage of the word. The space-time continuum of the General Theory of Relativity must have additional properties. What are they? Again, our geometrical intuition comes to help. We know that the properties of geodesics depend on the curvature of the geometrical space. As a simple example let us take a two-dimensional space, a surface. If this surface is flat, the geodesics on it are ordinary straight lines (in the sense of Euclidean geometry); if the surface is curved, *e.g.*, if it is part of the surface of a sphere, the geodesics are not straight any longer in the classic Euclidean sense. On the surface of a sphere the geodesics are great circles, and their projections onto a plane will appear as curves. Thus, our analogy will lead us to believe that, in general, space-time will be curved, while the space-time of the Special Theory was flat. The history of a particle will be described by a geodesic in this curved space-time. If we would project this geodesic onto the flat space-time used in the Special Theory, we would get a curve which is not a geodesic in this flat space-time. The deviation from a geodesic in flat space-time will become larger as the curvature of space-time increases. However, our considerations must embrace the fact that in Newtonian mechanics gravitational forces exist only in the neighbourhood of masses. This must find its counterpart in the geometrical picture. The reasoning is very simple. If gravitational forces find their expression in the curvature of space-time, and these gravitational forces were produced by masses in the Newtonian theory, then, in the General Theory, the masses must produce the curvature of space-time. Indeed, this seems to be the solution.

The structure of the Newtonian theory of gravitation is the following. Space and time are the stage upon which physical processes are displayed. In these processes the masses are acting directly upon each other. In the General Theory of Relativity, space and time are first fused together into a continuum called space-time. The geometrical properties of this space-time determine the evolution of the physical processes in space and time. The geometrical properties of the space-time continuum in turn

are determined by the masses (and physical processes) present in space and time. Thus in the latter theory we do not have anything external or uninfluenced, and the series of producers of mechanical phenomena is closed. (Observe, however, that this is not so for phenomena produced by electromagnetic and nuclear forces.)

These ideas and their mathematical formulation were finally given by Einstein in 1916. The geometrical properties of space-time are characterized by ten functions, which form the so-called metric tensor of this four-dimensional continuum. (Knowing the metric tensor, we can compute the separation of any two events in space-time.) Einstein formulated the field equations which relate these ten functions and their derivatives to ten other functions which describe the material content of space-time. These second ten functions form the so-called energy-momentum tensor, and they are the measure of the amount of energy (hence also mass) and momentum present in a specified portion of space at a given time.

The relationship mentioned has a very simple physical significance and is the mathematical expression of the idea that the curvature of space-time arises from the masses and their motion. From the metric tensor and the derivatives of its components we can form another tensor which is the measure of the curvature of space-time at a given point in space-time. Einstein's equations state essentially that the curvature of space-time at a given point in space-time is proportional to the amount of energy and momentum present at that point in space-time. Moreover, from the geometrical picture we can see that there always will be such a system of reference in which events in the immediate neighbourhood of the observer (local events) can be described according to the Special Theory. This follows from the fact that any curved space can be approximated locally by a flat space which is tangential to the curved space at that point. (For example, think of the curved space as the surface of a sphere, and the tangential flat space as the tangential plane.) Physically this corresponds to an accelerated frame of reference which has the same acceleration as caused by the gravitational forces at that point. (Thus again we can see how a more general theory embraces the special one as a limiting case.)

For any given material content, we can solve, in principle, the field equations and obtain from them the metric tensor. From the metric tensor we can compute the geodesics of space-time, which describe the history, and thereby the motion, of matter in the universe. The history of light rays can also be obtained, since they form a special class of geodesics called null geodesics. (These have no simple geometrical analogies from ordinary geometry.)

Logically, then, the theory rests in its modern form on two different postulates. First, the metric tensor shall satisfy the field equations; second, the history of a particle is given by a geodesic in space-time having the aforementioned metric tensor. Although we have seen that the second postulate played an important role in the formulation of the theory, the question arises whether we should not be able to discard it and extract all the information from the field equations only. Indeed, this proves to be the case. In a remarkable set of papers, Einstein and his co-workers attacked the problem in this fashion during the years 1938–49. Let us assume that mass points can be represented by singularities of the metric tensor. If, then, we want to have a solution for the field equations, the singularities must satisfy certain conditions. These conditions turn out to be just the equations of motion of mass points.

Now what about the experimental verification of the theory? The theory was subjected to three important tests. First, we can compute the orbits of planets from the General Theory. Barring the planet Mercury, the difference between the Newtonian orbit and the relativistic one is negligibly small for practical purposes. However, for Mercury, the Newtonian theory predicted the orbit incorrectly. Since the time of U. J. Leverrier, the French astronomer, it was known that there is a discrepancy between the observed motion of the Mercury perihelion and the one predicted by Newton's theory, even if we take into account the perturbations caused by the other planets. The first real success of the General Theory came when Einstein showed that this discrepancy disappears if we perform the calculations relativistically (*see* MERCURY).

There are two other effects predicted by the General Theory, both concerning the propagation of light. According to the General Theory the world lines of light rays must also be geodesics (null geodesics). Consequently the propagation of light will also be influenced by the presence of masses. For this reason light rays will be deflected from their original paths if they pass in the neighbourhood of bodies. If these bodies are very large, the effect can be observed. (Actually, rays which pass the object near enough will circle around it a few times before they go off to infinity!) The most suitable large mass at our disposal is the sun. The measurements can be performed in the following fashion. First we take a photograph of a part of the sky when the sun is not in that neighbourhood. Next we take one when the sun is there. Naturally, the latter picture has to be taken during a total eclipse; otherwise, we will not see the nearby stars at all. If the sun deflects the light rays, the angular distance between two stars lying at diametrically opposite sides of the sun must be larger on the second picture than on the first one. All measurements have shown the effect to be present. The precise evaluation of the numerical magnitude, however, is very difficult on account of experimental complications. The theoretical value is 1.74 sec. The first five experimental observations made scatter around this value, and each observation has a probable error large enough to embrace the theoretical value. (Two of the five observations took place in 1919, and one each in 1922, 1929 and 1951.)

The third experiment concerns the frequency shift of spectral lines emitted by atoms located in a gravitational field. We have already mentioned in discussing the Special Theory that atoms can be considered as clocks, since the radiation emitted by them has a periodicity, the frequency, which can be used to measure time. One of the predictions of the General Theory is that clocks in a gravitational field run slower than the same clock would run if the gravitational field were not present. Consequently, the slowing down of an atomic clock should mean the emission of light with a smaller period and thus a frequency shift in the spectral lines toward the red. All investigations have confirmed the existence of this effect. However, for atoms located on the surface of the sun, there are so many other disturbing factors which modify the effect that we hardly can attach great significance to the numerical values obtained for the red shift caused by the sun. On the other hand, measurements performed on light emitted by the companion to Sirius give the same order of magnitude as that predicted by the theory. (*See* also NEBULA: *Red Shifts and Expansion of the Universe.*)

In our discussion which led up to the formulation of the General Theory we have reduced the concept of gravitational force to that of inertia, eliminating the idea of force (at least the idea of gravitational force). We have done this by agreeing that the world line of a particle should be a geodesic in space-time. The action of other bodies manifests itself only by changing the geometrical properties of space-time.

However, we can now think of this in another fashion. If gravitation could have been conceived as a sort of mutual interaction of bodies (and of course we now have reduced the idea of gravitation to that of inertia) then could we perhaps conceive that inertia is actually a manifestation of a mutual action between bodies? As far as the histories of particles are concerned, we have already done that. But the inertial properties of matter find their expression also in the mass of bodies. So the question arises whether the concept of mass does not depend essentially on the existence of other bodies in the universe. Ernst Mach, an Austrian physicist, first posed this problem, before the advent of relativity theory. It seems that the General Theory suggests an affirmative answer. It follows from the theory that (1) the mass of a body increases when ponderable masses approach it; (2) if neighbouring masses are accelerated there is a force acting on the body (in the same direction as the acceleration); and (3) a rotating hollow body creates a field of force inside itself, a field which acts on particles inside the hollow body. These effects are much too

small (for ordinary bodies) to be observed. However, it might be possible that if the rotating masses are of cosmic magnitude, of the size of galaxies, for example, the effects on light rays could be detected. The questions raised by Mach cannot be answered from the principles of General Relativity alone, and further cosmological considerations are needed.

Another interesting inference we can draw from the General Theory is the way gravitational disturbances are traveling. This is of great interest, since one of the chief objections to Newton's theory was the instantaneous action of gravitational forces; *i.e.*, their infinite speed of propagation. The results are the following. Moving bodies, on account of their motion, emit a weak gravitational field in the form of waves. These waves travel with the velocity of light. At a great distance from the source the waves are transverse and polarized. The energy loss of the source due to this radiation is very small, being proportional to the inverse fifth power of the velocity of light. For double stars the energy loss per year would be about 10^{-12} part of the total energy.

Until now we have discussed how individual masses influence the geometry of space-time. The result has shown that in the main the Newtonian conclusions were good approximations, though the concepts invoked were of an entirely different nature. This was connected with the smallness of the masses, distorting only a little the flatness of space-time. If this be the case, we may reasonably expect that great differences may arise if we consider problems which entail the universe as a whole, considering all the masses in the universe. In other words we may expect that the cosmological theories stemming from the General Theory of Relativity can be of an entirely different nature than the Newtonian ones. Relativistic cosmologies vary in scope and importance, and though some of them describe part of our experiences correctly, none can be singled out as the best. *See* COSMOLOGY; COSMOGONY.

UNIFIED THEORIES

The General Theory of Relativity has eliminated the concept of gravitational forces. The "guidance" of particles does not take place by a direct interaction between them, but is accomplished by the geometrical structure of space and time. Gravitational forces, in the Newtonian sense, arise only if we refuse to interpret properly the geometry of space-time.

Naturally this makes us wonder whether the other existing forces, electromagnetic and nuclear, are also merely misinterpretations of the geometry of space-time. Our aesthetic sense would be greatly pleased if these forces were found to stem from the same origin as the gravitational forces.

There were numerous attempts to endow space-time with such a geometrical structure from which the existence of the other forces would follow. However, while nature gave us a guide in the case of the gravitational forces, to wit, the similarity between fictitious and gravitational forces, we do not see any simple or suggestive relation between the gravitational forces and electromagnetic and nuclear forces. In addition to this, it is also possible that unification cannot be achieved in this fashion. We know now that the description of the microscopic properties of matter and its interaction with radiation brings entirely novel features to physics, features which are dealt with in quantum theory (*see* QUANTUM MECHANICS). These features are not present in the General Theory; and it is quite possible that unification has to proceed via a theory that embodies the quantum aspects. (There were attempts to introduce the quantal aspects by formal manipulations in the General Theory [quantization of the gravitational field]. The nonlinearity of the gravitational field equations makes this approach somewhat ambiguous. For weak gravitational fields the quantization is mathematically unambiguous; the results would indicate that the gravitational field has a particlelike aspect where the particles have a spin two. [Compare this with the electromagnetic field, which, upon quantization, also acquires a particlelike aspect. The particles there are called photons.])

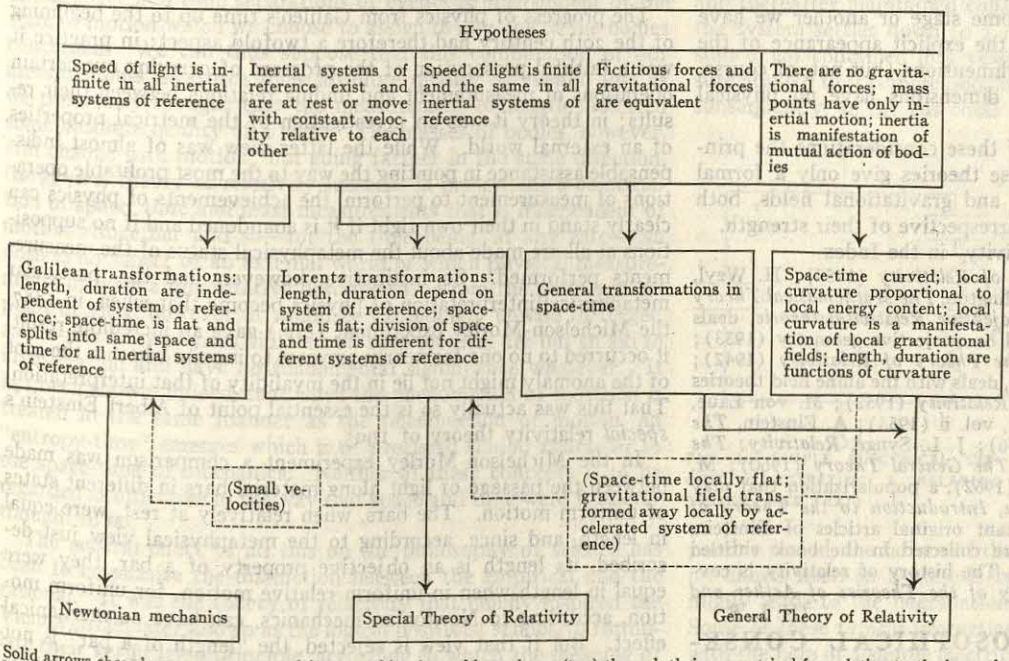
The general trend toward constructing a unified field theory is somewhat as follows: the Riemannian geometry of four dimensions, which described the geometry of space-time in the General Theory of Relativity, has no available functions which could be used to describe other fields of forces. Consequently we have to enlarge this geometry in such a fashion that just the sufficient number of functions appears.

If the unification extends over the gravitational and electromagnetic fields there will be at least 14 functions needed, 10 to describe the gravitational fields as in the General Theory and at least 4 to characterize the electromagnetic field, as in Maxwell's equations. Of course the unification may bring in some additional functions, too, just as in the General Theory 10 functions are needed to characterize the gravitational field completely, while in the Newtonian theory one was enough.

Suppose we have some ideas about what this geometry should be; what will then be the essential features of the theory? First, it must furnish a sufficient number of equations from which we can determine the functions describing the fields. Next, it should furnish in some fashion the equations of motions of charged and uncharged particles. If possible, it also ought to furnish a good definition for particle (as, for example, in the General Theory a mass point was a singularity of the gravitational field). Finally, we would expect that the fields will be, in general, tangled up (otherwise we would have only a formal unification), and will reduce to distinct electromagnetic and gravitational fields only under certain conditions, which, loosely speaking, would correspond to weak fields. The theory also should furnish the condition for weakness. If we want to incorporate the nuclear forces, we have to include in our program the description of additional fields, called meson fields.

This alone is already a formidable program. However, it is aggravated by the following problem. Suppose we have estab-

Outline of Hypotheses and Their Interrelationships



Solid arrows show how we may proceed from combinations of hypotheses (top) through their geometrical formulation to the laws of Newtonian mechanics and the Special and General theories of relativity. Dotted arrows show ways of passing from one theory to another by using the approximations shown in the dotted boxes.

lished tentatively a system of geometrical field equations. The functions, or field components, which are connected in this way have to be identified now with physical quantities, and the equations must be identified with physical field equations. This is not at all so simple as it may sound, and ambiguities may arise. This difficulty of interpretation is a rather novel feature of our unification problem, and it is intimately linked with the fact that our generalization proceeds from mathematical considerations and not from physical ones, which immediately would have given a meaning to the mathematical quantities used to represent the physical observables entering these considerations.

The loosening up of the geometrical structure to accommodate the additional field variables was pursued in two rather different ways. One way retained the idea of a four-dimensional continuum as the playground of physical phenomena, but used a non-Riemannian geometry in place of the Riemannian geometry which described space-time in the General Theory. The other way used a higher-dimensional continuum and projective or conformal geometries (*see* UNIFIED FIELD THEORY).

It is not easy to tell how far these attempts will prove successful. On the one hand, we cannot see clearly the conclusions which can be drawn because of the mathematical complications. On the other hand, as we have mentioned, the physical interpretation is in general far from being evident, and for this reason the interpretation and the mathematical development must proceed together. This complicates both the mathematical understanding and, thereby, the hope of experimental verification or refutation.

However, there is in both theories one prediction, obtained by Erwin Schrödinger, which in principle makes possible an experimental test. Alas, the effect is too small to be measured. This effect is the following: if in a region of space-time gravitational and electromagnetic fields are present simultaneously, an electric current field must be present in the same region, in general. On the surface of the earth, where gravitational and magnetic fields are simultaneously present, this would correspond to a small additional magnetic field, the strength of which is of the order of r/R times the primary magnetic field strength (the latter being about one-third gauss). The factor r/R is fantastically small, r being the gravitational radius of the earth (a few centimetres) while R is the actual radius of the earth (about 6.4×10^8 cm.).

It is much more difficult to give a coherent and simple account of the unified theories which use higher dimensional geometries. In all these cases the additional dimensions have no physical significance and their introduction is purely formal. The additional dimensions simply enable us to obtain enough functions to describe the different kinds of fields. At some stage or another we have to eliminate, by some assumption, the explicit appearance of the variables describing the additional dimensions (but not, of course, the additional fields), since these dimensions have no physical significance.

Apart from the formal nature of these considerations the principal difficulty is that most of these theories give only a formal unification of the electromagnetic and gravitational fields, both fields remaining clearly separated, irrespective of their strength.

(N. L. B.)

RELATIVITY: PHILOSOPHICAL CONSEQUENCES. The most important philosophical consequence of the theory of relativity is the clarification it has brought into the relations between science and philosophy. The position may be briefly summarized as follows. Up to the 17th century the subject matter of these studies formed a unity, the rudiments of that which we now call science being simply a part of a larger whole. A rift then appeared and gradually widened until, by the beginning of the 20th century, science and philosophy had become quite distinct and a person expert in one was usually very inexpert and ill-informed in the other. The effect of the relativity theory was to re-establish physics on a philosophical basis and thereby to elucidate certain bewildering implications of current research.

More particularly, the position was this. The general problem of philosophy is to give a rational account of experience with the minimum of presuppositions. Consequently it was not originally presupposed that physical experience must be regarded as an effect on our senses of an objectively existing external world having certain definite and ascertainable properties: that was a matter for discussion, and both affirmative and negative answers were given. Modern science, however, originated in the determination to ignore the metaphysical question and to accept experience as an object of study, whether or not it was "real." Thus Galileo discovered the law of falling bodies by measuring how the space covered varied with the time of fall. By carrying out certain processes of measurement he obtained results which stood in a certain relation to one another, and this relation remained true whatever metaphysical status one assigned to motion.

This became the origin and type of a large body of investigation which, by reason of its distinctive character and its rapid growth and success, came to be regarded as something other than traditional philosophy and was given the name "science." Nevertheless, it was still an attempt to give a rational account of experience with the minimum of presuppositions. Moreover, although it needed no supplement, it was in fact coupled from the beginning with a particular view of what the measurements signified. Galileo, for instance, supposed that they represented the magnitudes of certain characteristics of the external world which he regarded as possessing only mechanical properties such as size, shape, position, motion; other qualities (*e.g.,* colours, sounds, temperatures) he thought were not properties of the bodies which seemed to possess them but were contributed by the observing subject. This view was tenable in his day since he was unable to measure such things; but after the invention of thermometers, spectroscopes, etc., there remained no reason for distinguishing these so-called secondary qualities so fundamentally from motions and shapes, and they were gradually put back into the external world and included among the objectively existing properties of bodies, which science investigates.

The progress of physics from Galileo's time up to the beginning of the 20th century had therefore a twofold aspect: in practice it was a faithful prosecution of the program of carrying out certain operations of measurement and finding relations between their results; in theory it was an investigation of the metrical properties of an external world. While the latter view was of almost indispensable assistance in pointing the way to the most profitable operations of measurement to perform, the achievements of physics can clearly stand in their own right if it is abandoned and if no suppositions at all are made about the metaphysical status of the measurements performed. So instinctive, however, had this particular metaphysical interpretation of physics become that when, in 1887, the Michelson-Morley experiment (*q.v.*) gave an incredible result, it occurred to no one for nearly 20 years to inquire whether the root of the anomaly might not lie in the invalidity of that interpretation. That this was actually so is the essential point of Albert Einstein's *special* relativity theory of 1905.

In the Michelson-Morley experiment a comparison was made between the passage of light along material bars in different states of uniform motion. The bars, when relatively at rest, were equal in length, and since, according to the metaphysical view just described, its length is an objective property of a bar, they were equal in length when in uniform relative motion, for uniform motion, according to Newtonian mechanics, can have no mechanical effect. But if that view is rejected, the "length of a bar" is not an objective property but simply the result obtained when a particular operation of measurement is made. Now the operation for

measuring length was well-known, but it required that the body measured must be at rest with respect to the measuring scale; it was inapplicable if the body was moving along the scale. Hence one had no right to speak of the "length" of a moving bar. This was not because the length, an objectively existing property, could not, because of practical difficulties, be ascertained. It was because one had no right to use the word until one had the result of a particular operation to which to apply it, and no such operation had been devised for a moving body.

The theory of relativity prescribed an appropriate operation, and the experiment was then satisfactorily explained. This belongs to physics, but one aspect of it has philosophical implications. The reason why the ordinary operation for measuring length was inapplicable to a moving body was that the scale readings for the two ends of the bar varied with time when the body was moving. To get a definite result, therefore, they had to be taken simultaneously. Hence one had to know how to determine that two events at different places occurred at the same time, and on analysis it appeared that this was impossible without some arbitrary stipulation. Here again, then, the idea of something existing objectively which physical measurement revealed had to be given up. It was not that, because of practical limitations, we could not determine which of a number of spatially separated events were simultaneous. There was no meaning in speaking of the simultaneity of such events until one had prescribed a process for determining it, and there was a wide degree of liberty in prescribing such a process.

Physics was thus thrown back on the unadorned description of itself as the discovery of relations between the results of chosen operations of measurement. This description adequately covered the whole of physics from Galileo's basic discoveries onward; but the metaphysical accompaniment that had provided the imagination with a model and the experimenter with a guide was now proved misleading. The philosopher must henceforth interpret physics in terms of operations and their results alone, leaving external existences out of account. But the physicist, finding a picture of an external world indispensable, began to devise a better one. In the old picture the world consisted of pieces of matter, measured essentially by their mass, moving about, without thereby becoming changed, in an infinite extension called space and an independent extension called time. According to the revised picture, matter, space and time are no longer independent but merge into a single continuum, space-time—a device made possible by the fact that, according to the definitions adopted for the length of moving bodies and the time relations of separated events, a certain combination of the space and time separations of events is independent of the state of motion which we choose to assign to any one of the bodies concerned. We can thus suppose that this combination of our measurements measures some absolute quality of events, just as we previously thought that the measurement of length indicated some absolute quality of a body. The masses of bodies, however, still change with motion; but going farther in the same direction, the *general* theory of relativity succeeds in prescribing a combination of space, time and mass measurements that is independent of motion altogether and so—for the time being, at any rate—can pose as an aspect of an external world of which physical measurements provide a quantitative description. From the philosophical point of view, however, it would be exceedingly unwise to forget, as pre-relativity physics did, that all such pictures are but an aid to investigation and have no fundamental significance whatever. It has been shown, indeed, that when the phenomenon of radiation is treated in the same manner as the phenomenon of motion, an "entropy-time" emerges which is of precisely similar character to the space-time of mechanics. Neither of these concepts is to be regarded as objective in the way that space and time were formerly thought to be.

The general effect of all this on the philosophy of science has been to emphasize the distinction between the empirical and the rational. It was the theory of relativity that chiefly inspired the Vienna circle, later known as the logical positivist school, to formulate their verification principle, according to which the meaning of any statement is determined by the empirical steps necessary to verify it. Statements that are not susceptible of empirical verification (or falsification) are either rational (*i.e.*, tautological) or nonsensical. The absolute simultaneity of separated events is a typical example of a nonsensical concept since it is neither empirically determinable nor a rational necessity.

Precisely the same classification was made by Sir Arthur Eddington, who also was inspired primarily by the relativity theory; but whereas the logical positivists have developed their views in the direction of an analysis of language in general, without special reference to physics, Eddington undertook the detailed examination of physical theory. He was led to the conclusion that the whole scheme of physical law was rational in nature and could have been derived without any experience at all of actual events. In other words, although, as a historical fact, the laws have been derived by studying the results of measurements, they are actually so abstract that they characterize only the nature of the processes of measurement and are therefore independent of the particular results that applications of those processes have yielded.

Eddington's views on this point are not generally accepted, but it must be acknowledged that they are either not understood or misunderstood by the majority of critics—a fact for which Eddington himself is not entirely blameless. His mathematical work is not without error, and his gift for picturesque language led him at times to sacrifice rigour of expression for the sake of a vivid metaphor. He himself advanced, as the crucial argument for his view, the claim that he had derived all the dimensionless constants of physical theory from purely rational considerations; but the derivation involved such a wealth of little-known mathematical processes that a lengthy analysis was required before it could be finally appraised. One common misunderstanding, however, can here be removed: he did not claim that the whole course of physical experience could have been predicted; on the contrary, he held that none of it could. The laws of physics, he believed, were not the laws of behaviour of observed bodies but those of postulated entities. Only when observed bodies were identified with such entities were the laws applicable to them, and any lack of agreement would indicate, not a failure of the laws, but false identification.

RELAXATION PHENOMENA, in physics, are phenomena associated with the approach of a system to equilibrium (*see* PHASE EQUILIBRIA). If a force is suddenly applied to a system and thereafter maintained constant, some time may elapse before the system settles down to a new state of equilibrium. For instance, gas contained in a vessel contracts immediately the pressure applied to it is increased, and becomes warmer in the process; subsequently, as the gas cools to the surrounding temperature, a further slow contraction occurs. A more extreme example of relaxation is to be found in a substance like pitch, which reacts as a solid to forces of short duration, but as a liquid to prolonged stress. In such cases one may consider the system to require a certain characteristic time to stabilize itself, and to exhibit different behaviour according as the duration of the stress is much longer or much shorter than this. If the duration is comparable with the characteristic time, or if the stress is periodic with a comparable period, the failure of the system to achieve internal stability shows itself in hysteresis behaviour of the sort which commonly leads to the degradation of mechanical energy into heat. Some of these typical properties may be examined in more detail with the help of a simple electrical circuit, which serves as a useful model of a relaxing system.

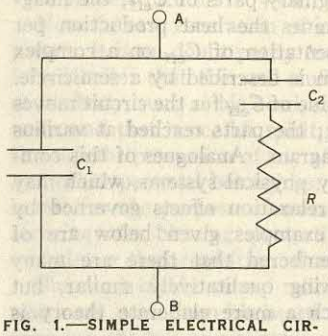

FIG. 1.—SIMPLE ELECTRICAL CIRCUIT ILLUSTRATING A RELAXING SYSTEM (SEE TEXT)

The circuit is shown in fig. 1 and consists of two capacitances,

C_1 and C_2, and a resistance R. If a voltage V is applied suddenly (at time $t = 0$) across the terminals AB, the charge that flows will be as represented by the graph in fig. 2; there is an initial immediate flow of C_1V, charging up the condenser C_1, and a slower charge flow amounting in all to C_2V as current flows through R to charge the condenser C_2. This second process is described by an exponential law, the charge on C_2 being given by $C_2V\ (1 - e^{-t/\tau})$, in which the characteristic time τ (the so-called relaxation time) is equal to C_2R. Now consider the application of an alternating voltage across AB. If the angular frequency ω is low, so that $\omega\tau \ll 1$, the voltage will change sufficiently slowly that there is time for C_2 to receive very nearly as much charge as if the voltage were steady, and under these conditions the circuit will behave like a condenser of capacity $C_1 + C_2$. If, however, the frequency is high, so that $\omega\tau \gg 1$, there will be insufficient time for C_2 to receive any charge before a reversal of the voltage tends to remove it again and therefore C_2 will remain virtually uncharged; thus the circuit will behave like a condenser of capacitance C_1. At intermediate frequencies, when $\omega\tau \sim 1$, the effective value of the capacitance will take intermediate values and there will also be significant heat production by the currents flowing in the resistance. Fig. 3 shows on a logarithmic frequency scale the variation of the effective capacitance and the heat production per cycle; the latter varies in proportion to the frequency at low frequencies, and in inverse proportion at high frequencies. Two points may be particularly observed about the behaviour of this model. The first is that the transition is extended over a wide band of frequencies, *i.e.*, values of $\omega\tau$ ranging between $\frac{1}{10}$ and 10; the second is that the height of the peak representing resistive losses is directly related to the difference between low- and high-frequency capacitances. This is particularly clearly shown by a graph of the (complex) effective capacitance of the circuit. If the impedance Z between A and B is used to define formally the effective capacity C_{eff} by the equation $Z = 1/i\omega C_{\text{eff}}$ the two curves in fig. 3 represent the real and imaginary parts of C_{eff}; the imaginary part is resistive and determines the heat production per cycle. In fig. 4 is shown a representation of C_{eff} on a complex diagram, where the whole variation is described by a semicircle. As the frequency is increased the value of C_{eff} for the circuit moves anticlockwise from $C_1 + C_2$ to C_1; the parts reached at various frequencies are indicated on the diagram. Analogues of this complex diagram are observed in many physical systems, which may be inferred therefrom to exhibit relaxation effects governed by a simple exponential law. The examples given below are of this type, but it should be remembered that there are many more complicated examples showing qualitatively similar, but not identical, behaviour, for which a more elaborate theory is needed.

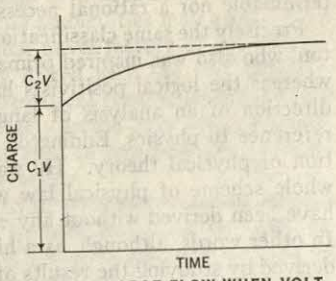

FIG. 2.—CHARGE FLOW WHEN VOLTAGE IS APPLIED TO TERMINALS AB OF FIG. 1

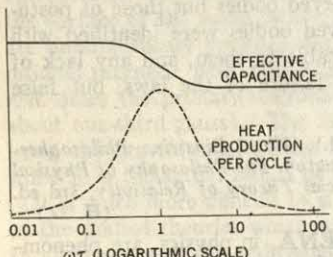

FIG. 3.—VARIATION OF EFFECTIVE CAPACITANCE AND HEAT PRODUCTION PER CYCLE

Alternating voltage across AB of fig. 1

Systems of which the above circuit is a helpful model are to be found in almost all branches of physics, but perhaps particularly in the fields of elasticity and acoustics. One of the most famous examples concerns the propagation of ultrasonic waves in gaseous carbon dioxide (CO_2). The velocity of sound in a gas is expressed by the formula $\bar{v}\sqrt{\gamma/3}$, in which $\bar{v}$ is the root mean square velocity of the molecules and γ is the ratio of the principal specific heats C_p/C_v; since $C_p - C_v$ is equal to R, the gas constant, γ may also be related to C_v by the formula $C_v = R/\gamma - 1$. Now it is found experimentally that sound waves of a frequency less than 2 kc. per second travel at a velocity of 268 m. per second in pure CO_2, while if the frequency is greater than 200 kc. per second the velocity is increased to 280 m. per second. Since $\bar{v}$ does not depend on the frequency this result may be interpreted to mean that the effective value of γ, or C_v, depends on the frequency. In fact the low-frequency value of C_v determined by this argument is 6.85 cal. mole^{-1} degrees^{-1} and the high-frequency value 4.95 cal. mole^{-1} degrees^{-1}. The latter value is almost precisely that predicted by the Maxwell-Boltzmann Law for a gas molecule having five degrees of freedom, and herein is an interpretation of the experiment. When a portion of the gas is alternately compressed and expanded by the passage of the wave, kinetic energy is transmitted to or extracted from the molecules by collisions—in other words, on adiabatic compression the gas is heated. This kinetic energy is taken up immediately in translational energy of the molecules, and by collision is shared almost as quickly with the rotational motions of the molecules. If enough time is allowed, ultimately some of this energy will be transmitted to the vibrational motions of the atoms constituting the molecule, but this takes much longer. The main reason is that the vibrational motions are quantized and energy can be exchanged only in units of $h\nu$, where ν is the vibrational frequency involved; in CO_2 all the quanta $h\nu$ of the various vibrations are several times higher than the mean kinetic energy of the molecules, so that only the rare collisions between exceptionally energetic molecules are effective in transferring energy. There is thus a characteristic relaxation time τ, about 10^{-5} sec. in pure CO_2 at room temperature, for imparting energy to the vibrations. If the angular frequency ω of the wave motion is such that $\omega\tau \ll 1$, the vibrational modes are able to come into thermal equilibrium with the external (translational and rotational) modes, and the value of C_v reflects about seven degrees of freedom. But if $\omega\tau \gg 1$, the vibrational modes are unable to exchange energy and C_v has a value corresponding to only the five external modes. The analogy between the internal and external modes in this example, and the capacitances C_1 and C_2 in the model analyzed above, should be obvious. At a frequency of 20 kc. per second, when $\omega\tau \sim 1$, the peak of resistive loss in the model is paralleled by a peak of attenuation of the sound wave; the energy in the sound wave is halved in a distance of only $5\frac{1}{2}$ wave lengths, or $7\frac{1}{2}$ cm. (*See* also CHEMISTRY: *Physical Chemistry: The Maxwell-Boltzmann Law.*)

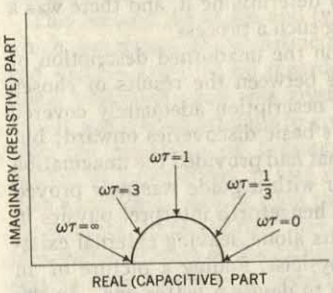

FIG. 4.—EFFECTIVE CAPACITANCE OF THE SYSTEM IN COMPLEX PLANE

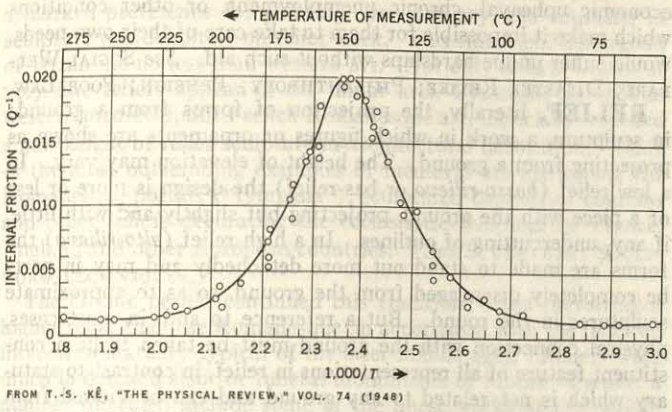
Data in Fig. 3 have been replotted with $\omega\tau$ entering as a parameter

Many other examples of this type of relaxation have been studied, as well as a similar type associated with structural rearrangements, particularly in liquids and solids. Detailed discussions of many will be found in the references below, but one example must suffice here, elastic relaxation of certain cubic metals containing dissolved impurities. When carbon dissolves in tantalum, the atoms occupy interstitial sites which may be said to be of three kinds, according as the nearest tantalum atom lies in the x, y or z direction, these three directions defining the cube axes of tantalum. As long as the tantalum is unstrained, there is no preference among sites, which are all equally likely to be occupied; but if the tantalum be compressed along the x-axis, the x-sites are deformed differently from the y- and z-sites, and in equilibrium the two types of site will become differently occupied by the migration of carbon atoms toward the preferred sites. The deformation resulting from a given compressional force now depends on whether enough time is given for migration to occur. In fact fig. 2 may be interpreted as a schematic graph of the deformation due to a constant force, while the curves of fig. 3 serve to represent the variation of compressibility and elastic loss with frequency when a periodic force is applied. The relaxation time

τ is related to the time taken by carbon atoms to diffuse from site to site and is highly temperature-dependent according to the law $\tau \propto e^{H/RT}$, where H is a heat of activation. Thus if the frequency is kept constant and the temperature varied, $log\ (\omega\tau) =$ constant $+ H/RT$ and a plot of elastic behaviour against $1/T$ should look like fig. 3. This is shown in fig. 5, from the scale of



FROM T.-S. KÊ, "THE PHYSICAL REVIEW," VOL. 74 (1948)

FIG. 5.—VARIATION WITH TEMPERATURE OF ELASTIC LOSS IN TANTALUM DUE TO 0.013% DISSOLVED CARBON

which it may be immediately deduced that H for this diffusion process is 25,000 cal. per molecule. Relaxation peaks of this nature are found in many solids and are often the most sensitive way of detecting the presence of certain impurities; *e.g.*, it is possible to trace one part in a million of carbon in iron. Finally, it should be mentioned that exactly analogous phenomena are observed when sound waves pass through mixtures of substances in chemical equilibrium, when oscillatory electric fields are applied to metals and to many dielectric substances and when oscillatory magnetic fields are applied to many paramagnetic substances. Detailed study of these provides information on the rate at which equilibrium is attained and hence may suggest the mechanisms that are operative in establishing the state of equilibrium.

(A. B. PI.)

RELIC, in the strict sense, designates the mortal remains of a saint; in the broad sense, it covers also objects that have been in contact with him. The basis of Christian cult veneration of relics is the conception that reverence for the relics redounds to the honour of the saint (relative *dulia, dulia* being the reverence paid to the saint himself). While expectation of favours may accompany the devotion, it is not integral to it.

Christian Church.—The first Christian reference (Acts 19: 12) speaks of handkerchiefs carried from the body of St. Paul to heal the sick. About A.D. 156, the *Martyrdom of Polycarp* describes the bones of the Smyrna bishop as "more valuable than precious stones," yet distinguishes between the love for Polycarp and the worship of Christ. In Western Europe, an epigram of Pope Damasus (366–384) shows saints' remains in the Roman cemetery of Calixtus to have been the object of public cult. Several decades later, the protests of Vigilantius of Aquitaine against relic veneration elicited the retort in 404 of St. Jerome's *Letter CIX* ("We honour the relics of martyrs that we may adore him whose martyrs they are") and in 406 his *Treatise Against Vigilantius.*

In 356 the relics of St. Timothy and in 357 those of SS. Andrew and Luke were translated to the new imperial capital of Constantinople. Sometime before 431, Theodoret of Cyrrhus reports that a single saint's relics were often divided among many villages (*Cure of Pagan Diseases,* viii, 10). At Rome, however, in 594 Pope Gregory the Great refused to divide the relics of St. Paul, consenting only to the distribution of cloths (*brandea*) touched to the remains.

The discoveries, real or reputed, of Christ's cross at Jerusalem (probably 320–337) and of the bodies of SS. Gervasius and Protasius at Milan in 386 and of St. Stephen at Kaphar-Gamala, in Palestine, in 415 contributed to the multiplication of small relics and to an emphasis upon their miraculous possibilities. With Gregory of Tours (d. 594), this emphasis is strong; with Caesarius of Arles (d. 542), it is nil, pointing up the role played by temperament in devotion. Generally, the Middle Ages enlarged the expectation of miracles, while the flood of Oriental relics into Europe at the time of the Crusades raised serious question as to their authenticity and ethical procurement. Problems of this nature had arisen earlier: *c.* 400 St. Augustine had complained of the "hawking about of the limbs of martyrs, if indeed of martyrs." However, as medieval theology was formulated in St. Thomas Aquinas' *Summa theologica* (III, q. 25 a. 6), it hewed close to the Augustinian thesis (*City of God,* i, 13) that it is natural to cherish the remains of the saintly dead and it found sanction for such cult in God's working of miracles in the presence of relics.

The attitude of the 16th-century Reformers toward relics was uniformly negative. In 1537, the Lutheran Schmalkaldic Articles called them "useless" while in 1553 the Anglican Articles of Religion designated their adoration a "fond thing vainly invented."

Roman Catholic thought defined in 1563 at the Council of Trent and currently expressed in the *Codex juris canonici* (*c.* 1200, *c.* 1276–89) of 1917 maintains the liceity of relic veneration, requires the presence of relics in consecrated altars, and lays down rules to assure authenticity and to exclude venal practices; excommunication is the punishment for those who sell genuine relics or who manufacture or distribute false ones. Among the relics most widely venerated are the Holy Coat of Trier, of which there are two, one in the Trier Cathedral and one at the parish church at Argenteuil, both believed to be genuine garments of Christ's; Santiago de Compostela, traditionally the burial place of St. James the Apostle; and the Holy House at Loreto, near Ancona, Italy, believed to have been the house inhabited by the Virgin Mary at the time of the Annunciation and to have been miraculously moved from Nazareth to Dalmatia and thence to Loreto in the 13th century.

For the Orthodox Churches, the approbation extended to relic cult by the Eastern Fathers and the second Council of Nicaea in 787 proves normative. In practice, however, Orthodox devotion focuses upon icons rather than upon relics, though the antimension (the cloth upon which the Divine Liturgy is celebrated) always contains a relic.

(H. G. J. B.)

Other Religions.—*Islam.*—Like Christianity, Islam has had a cult of relics associated with its founder and saints. In Islam, however, the use of relics has had no official sanction; indeed, Muslim theologians have frequently denounced the veneration of relics and the related practice of visiting the tombs of saints as conflicting with the Prophet Mohammed's insistence on his own purely human, nondivine nature (Koran iii, 144) and his harsh condemnation of idolatry and the worship of anyone other than God himself (Koran iv, 48 ff., 116 ff.; etc.).

Nonetheless, veneration of relics has found a place in Muslim piety. It is no doubt partly rooted in the ancient and universally found belief that the soul-stuff of a man pervades certain parts of his body, such as his head, saliva, blood, hair, teeth, and fingernails, and that hence his spiritual powers are available to another through the possession of any of these parts, or even of his clothing and other personal belongings. Thus, the Muslim's use of relics is not for the purpose of worship, strictly speaking, but for the securing of a blessing, protection against evil, the working of a miracle, or the acquisition of magical power or spiritual grace.

The most highly valued relics are those of the Prophet, among which are hairs from his beard and head, a tooth, a prayer mat, a wine jar, the hilt of his sword, a spear and an arrow said to have been his, his staff and mantle, shoes and shirt, a stone reputedly bearing his foot imprint, and various manuscripts attributed to him.

Buddhism.—Relics have had a greater role in the life of Buddhism than in that of any other of the major non-Christian religions. Moreover, relic worship was canonically established in the religion from its earliest days. Tradition (Mahaparinibbana Sutta) states that the cremated remains of the Buddha (d. 483 B.C.) were distributed equally among eight Indian tribes in response to a demand for his relics. A stupa, or memorial mound,

was built over each portion of the sacred remains, as well as over the vessel used for measuring them out and over the collected ashes of the funeral pyre. Another tradition attributes to the great Indian emperor Asoka (3rd century B.C.) the distribution of the Buddha's relics among the 84,000 monasteries he is said to have built after his conversion to Buddhism. Other sources have also recorded the existence of shrines reputedly housing relics of the Buddha or of Buddhist saints and thus serving as important centres of popular pilgrimage and devotion. The Chinese Buddhist pilgrims Fa Hsien (5th century A.D.) and Hsüan-tsang (7th century A.D.), for example, speak of several such places in India and Ceylon, and others are known to have existed in southeast Asia, Tibet, and China.

The most important of the shrines are those that claim some part of the corporeal remains of the Buddha himself. Seven bodily relics (*saririka*) in particular are said to be "the Great Relics" of the Buddha: his four canine teeth, the two collarbones, and frontal bone. Of these the teeth have received the most widespread devotion, a number of shrines having been dedicated to them throughout Asia. Other shrines reportedly have housed certain personal possessions of the Buddha, most notably his alms bowl, which, like the Holy Grail in Christianity, is associated with a romantic tradition of wanderings.

In addition to the bodily remains and personal effects of the Buddha, those of great Buddhist saints and heroes are also venerated. In Tibetan Buddhism worship is accorded the carefully preserved bodies of the deceased priest kings (*see* DALAI LAMA), who in their lifetimes are regarded as reincarnations of a heavenly being, the Bodhisattva Avalokitesvara.

The intention of relic worship in Buddhism, whether of the Buddha or of a saint, is primarily that of engendering faith and true piety and of acquiring spiritual merit. However, there is also the belief that the supernatural power of the Buddha and the saints continues to work through their relics and the places in which they are deposited, effecting for the worshiper miraculous and magical deeds.

Hinduism.—In Hinduism, although images of divine beings have a major place in popular devotion, the veneration of relics as found in Christianity, Islam, and Buddhism is largely absent. This is largely due to two facts: Hinduism has no historical founder, as do the other three religions, and it tends to regard the world of physical, historical existence as ultimately an illusion (*maya*). Thus, the mortal remains and earthly possessions of religious heroes or holy men are not generally regarded as having particular spiritual value.

A notable exception, however, is found in the person of Chaitanya (*q.v.*), a 16th-century saint of Bengal who is worshiped as an incarnation of the Lord Krishna. A number of statues of Krishna are especially adored in the belief that Chaitanya left the phenomenal realm by "disappearing" into one or the other of them. Moreover several items believed to have been his personal possessions are venerated as holy relics—*e.g.*, an oar, a copy of the sacred scripture the Bhagavad Gita, and a stone reputedly bearing the impress of his body made when he slept upon it one night. In addition, although not in the strictest sense relic worship, the burial places of the remains of certain other holy men (such as Ramakrishna, Mahatma Gandhi, and Sri Aurobindo) are regarded as sacred. (H. P. S.)

Kennedy, *The Chaitanya Movement* (1925).

RELIEF, a term used colloquially to designate aid, either public or private, to persons who, because of natural disasters, wars, economic upheaval, chronic unemployment, or other conditions which make it impossible for them to take care of their own needs, would suffer undue hardships without such aid. *See* SOCIAL WELFARE; DISASTER RELIEF; PHILANTHROPY; PENSION; POOR LAW.

RELIEF, literally, the projection of forms from a ground; in sculpture, a work in which figures or ornaments are shown as projecting from a ground. The height of elevation may vary. In a low relief (*basso-rilievo* or bas-relief) the design is more or less of a piece with the ground, projecting but slightly and with little, if any, undercutting of outlines. In a high relief (*alto-rilievo*) the forms are made to stand out more detachedly and may in parts be completely disengaged from the ground, so as to approximate sculptures in the round. But a reference to and, in most cases, physical connection with the ground must be taken to be a constituent feature of all representations in relief, in contrast to statuary which is not related to any ground and can be viewed from all sides. The 19th century tendency to employ the term "bas-relief" indiscriminately for all kinds of relief, high as well as low, is unjustified linguistically and seems now to be subsiding.

Rarer forms of relief are the "sunk reliefs," especially of ancient Egypt, where the forms are carved in and beneath the surrounding ground rather than rising from it. Intaglio, likewise, is a hollow relief, but carved as a negative image like a mold instead of a positive form. Actually the most common use of intaglio is in engraved seals of precious stones or metal, designed to produce a positive imprint when pressed into a plastic material such as heated wax. However, intaglio techniques may also be used without such a purpose; *e.g.*, in the decoration of transparent materials such as glass.

Modes of representation and composition in relief are always determined by their dependence on the ground plane from which the forms emerge, or on which they are superimposed. In this important respect reliefs are more nearly related to painting than to the detached roundness of statuary. Ancient Egyptian art, which differentiated the various branches of art in the most systematic manner, from the beginning applied the same basic principles of representation to reliefs as to painting. Usually the design stands out from the ground in very low relief, however carefully modeled. Figures are shown sidewise, standing on base lines, and precisely outlined in conformity to the plane surface from which they are carved. As to their methods of representation, and regardless of their materials—wood, soft stones, hard stones or metal—they must therefore be classified with painting. Similar observations are true of other early arts, like those of Mesopotamia and the ancient near east.

High reliefs first became common in Greek art; notable examples are the Attic tomb reliefs, with individual figures or family groups shown almost in the round, of the 4th century B.C. On the whole the Greek reliefs, also, follow rather closely the development of contemporary painting. Sculptured friezes were often used in architectural decoration. A doubt may arise regarding the famous pedimental sculptures of Greek classical temples which are composed of large figures worked singly, and not physically connected with the ground, thus resembling free statues. (*See* GREEK ART; OLYMPIA; PARTHENON; etc.)

However, since these figures were placed in the pediments and consequently not seen freely but against a background wall, their compositions must in effect be regarded as a kind of high reliefs. Likewise in Roman art (*q.v.*), the pictorial character of the reliefs is undeniable. A rich field of study for the relation between ground and figures in classical reliefs can be found in the numerous sculptured sarcophagi which constitute one of the most representative achievements of Roman art during the 2nd and 3rd centuries A.D. Excellent examples of ancient relief are also available in the minor arts, both of Greece and Rome, especially in silver and ivory. (*See* SILVER AND GOLD WORK.) Moreover

the rapid expansion of the classical style in and beyond the Mediterranean area after the Hellenistic period gave rise to a flowering art of relief sculpture in the far east, first of all in the religious art of India.

It appears as a natural consequence of the classical tradition that during the early middle ages, a period which generally exhibits a marked preference for painting over statuary, the emphasis in sculpture was definitely on relief work. This statement holds good of Byzantine no less than western art. Not only does a wealth of very fine reliefs appear in the minor arts, Byzantine as well as western medieval, but French Romanesque art, especially, reached a new height of relief sculpture in architectural decoration. Some of the most outstanding examples of medieval art are among the Romanesque portals ("tympana"), sculptured capitals of columns and other reliefs decorating the ecclesiastic buildings of France, England and other European countries. (*See* SCULPTURE; SCULPTURE TECHNIQUES.)

The Gothic period continued this tradition, often preferring a higher relief than the Romanesque, in accordance with the renewed interest in statuary typical of the later middle ages. Reliefs were much in demand also for funeral monuments of bronze or stone, a number of which include some of the finest works of the period. The latest examples of Gothic relief art are the frequent carved altars, mostly of wood, and other church furniture of the "international style" shown in churches all over western and central Europe from Spain to Poland. (*See* WOOD CARVING: *European and American.*)

During the Italian Renaissance period the status of relief work among the total output of art begins to change. Between painting and statuary the number of reliefs decreases, except perhaps in the minor arts. No longer are certain places traditionally reserved for decoration in relief, as was true of the medieval church buildings. On the other hand the condition of representations in relief now became subjected to new studies and experimentation with a revisory intent, as a task of art different from both painting and statuary. The first striking results of the new trend are the bronze doors which Ghiberti created for the famous baptistery of Florence. Characteristic is the free play between high and low relief, from which a strikingly illusionistic style of composition can be derived, supporting the new interest in space as a subjective, visual experience.

Donatello further exploited these experiments, adding to the interplay of high and low relief the contrasts between rough and smooth surfaces, as well as between forms shown fully modeled and others only indicated in an almost painterly, impressionistic state of incompleteness. As a result, Florentine artists after Donatello pursued for a while two rather different trends regarding the treatment of reliefs. Typical of the one are the delicate and low reliefs in marble and terra-cotta, for which Desiderio da Settignano and Mino da Fiesole became best known. The other, more contrasting trend became incorporated in the relief style of Bertoldo and later, Michelangelo.

Baroque art continued these experiments, often on a very large scale. Characteristic are large compositions—a kind of marble painting—of which the Roman churches, especially, hold many excellent specimens. These compositions, because of their large size and high relief, often approach the effect of *tableaux vivants* shown in deep boxlike frames and special, stagelike conditions of lighting. L. Bernini's "Ecstasy of Sta. Theresa," with figures carved almost fully in the round but encased in a marble altar, in the church of Sta. Maria della Vittoria, Rome, offers a most impressive example.

Neoclassic art of the early 19th century, following a more puritan attitude toward artistic principles, temporarily revived experimentation with low reliefs, relying for effect on fine surface modeling and clarity of design. The works of Antonio Canova and Bertel Thorwaldsen are typical. However, on the whole the Renaissance concept of relief prevailed. Its dramatic and impressionistic possibilities were sensed keenly and employed vigorously by subsequent sculptors of the 19th century such as F. Rude ("The Marseillaise," decorating the Arc de Triomphe in Paris) and later, most famously, Auguste Rodin ("Portal of Hell" and other reliefs). In continuation of these trends relief techniques came to be used in modern art, not only for representational but also for abstract compositions which exploit freely the spatial element as well as the contrasts of light and shade, in reliefs conceived as a succession of overlapping planes. The latter concept, by its nature, often leads to a greater emphasis of the pictorial qualities inherent in relief art. It is typical of this situation that modern painters not infrequently show an interest in the art of relief as did Picasso, among others, during the evolution of his Cubism. *See* SCULPTURE; SCULPTURE TECHNIQUES; *see* also references under "Relief" in the Index.

RELIGION (ARTICLES ON). The article that follows must be considered to represent only a selection, and that somewhat arbitrary, of the *Encyclopædia Britannica* articles on religion. It attempts a logical organization, but logic, too, is sometimes defeated, since subjects of religious or quasi-religious nature overlap one another. This article largely ignores mythology and philosophy, both of which in some aspects are related to religion.

Judaism.—The leading articles are JEWS and JUDAISM, the former concerned chiefly with the history of the Jewish people, the latter with their religion. TALMUD deals with the most important (outside the Bible) Jewish writings, APOCALYPTIC LITERATURE, TARGUM and MIDRASH with other classes of writings. Holy days are discussed in JEWISH HOLIDAYS and SABBATH; LITURGY, JEWISH and SYNAGOGUE are related. JEWISH SECTS DURING THE SECOND COMMONWEALTH is concerned with the factions (Pharisees, Sadducees, etc.) that arose in Judaism in the centuries before and the 70 years after the beginning of the Christian era and that profoundly influenced Christianity as well as later Judaism. Later divisions in Judaism are KARAISM; CABALA; and HASIDISM. Aspects of Jewish history are the concern of the articles ANTI-SEMITISM; DIASPORA; MACCABEES; MARRANO; SANHEDRIN; SCRIBES; and SEPHARDIM, ASHKENAZIM, AND ORIENTAL JEWS, among others. Articles of Jewish interest that are only indirectly related to religion are HEBREW LANGUAGE; HEBREW LITERATURE; JEWISH ART; JEWISH PHILOSOPHY; YIDDISH LANGUAGE; and YIDDISH LITERATURE.

Christianity.—The Christian religion is dealt with exhaustively, beginning with the leading articles CHRISTIANITY and JESUS CHRIST, going on to APOSTLE; CHURCH: *The Religious Community;* EARLY CHRISTIAN CHURCH; COUNCIL, which outlines the controversies within the early and medieval church; ARIANISM, HOLY SPIRIT, NESTORIUS, MONOPHYSITES, TRINITY, etc., which are concerned with these controversies; and the heretical and schismatic movements that also were related—*e.g.,* ADOPTIONISM; MONARCHIANISM; SABELLIANISM; MONTANISM; DONATISTS; PELAGIUS. The basic articles on the church in the Middle Ages are ROMAN CATHOLIC CHURCH; PAPACY; COUNCIL; MONASTICISM; and articles on the great religious orders that arose during those centuries—*e.g.,* AUGUSTINIAN HERMITS; BENEDICTINES; CARMELITES; CARTHUSIANS; CISTERCIANS; FRANCISCANS. Also significant to the medieval period are articles on such divergent bodies as BOGOMILS; CATHARI; WALDENSES.

Christian Churches.—REFORMATION is the leading article on that subject, and the history of the Reformation is also discussed in LUTHERANISM; PRESBYTERIANISM; REFORMED CHURCHES; ENGLAND, CHURCH OF; CONGREGATIONALISM; and PURITANISM. Movements for ecclesiastical change that preceded the Reformation proper are the subjects of LOLLARDS and HUSSITES; Christian humanism is discussed in RENAISSANCE. METHODISM and BAPTISTS deal with major Protestant movements that arose after the Reformation, and there are articles on all the modern Protestant churches of substantial size. Religious bodies that fall outside the main stream of the Protestant Reformation are the concern of (for example) JEHOVAH'S WITNESSES; SALVATION ARMY, THE; UNITARIANISM; LATTER-DAY SAINTS, CHURCH OF JESUS CHRIST OF.

ROMAN CATHOLIC CHURCH and PAPACY are the main articles on Roman Catholicism. CARDINAL; CONCLAVE; and VATICAN are also dealt with at length. Disputes that arose within the church after the Reformation are the subjects of such articles as GALLICANISM; JANSENISM; MODERNISM, ROMAN CATHOLIC; and ULTRAMONTANISM. CATHOLIC ACTION and LITURGICAL MOVEMENT, ROMAN CATHOLIC are concerned with contemporary movements of importance. ORDERS AND CONGREGATIONS, RELIGIOUS provides a list of all the Roman Catholic religious orders of men, and there are separate articles on the larger orders and congregations. WOMEN'S RELIGIOUS ORDERS describes the history of the orders of women. CANONIZATION and SAINT; BREVIARY, MISSAL and HOURS, CANONICAL; MASS; and CANON LAW are among the many other articles that relate chiefly to the Roman Catholic Church.

ORTHODOX EASTERN CHURCH, the main article on the church in the east, outlines the reasons behind the east-west schism and refers to other articles on this subject. BYZANTINE EMPIRE also discusses the schism. There are separate articles on national Orthodox churches (*e.g.*, ALBANIA, ORTHODOX CHURCH OF; ORTHODOX CHURCH IN AMERICA; BULGARIAN ORTHODOX CHURCH) and on the four historic patriarchates of Constantinople, Alexandria, Antioch and Jerusalem. Subjects specifically related to the Orthodox Church are HESYCHASM; ICONOCLASTIC CONTROVERSY; and JERUSALEM, SYNOD OF.

The non-Chalcedonian ("Monophysite") Eastern churches are discussed in ANTIOCH, SYRIAN ORTHODOX PATRIARCHATE OF; ARMENIAN CHURCH; and COPTIC CHURCH.

Writings.—The article BIBLE outlines briefly each book of the Bible and indicates the groupings into which the books fall. BIBLE, TRANSLATIONS OF is concerned with that subject, EXEGESIS AND HERMENEUTICS, BIBLICAL with interpretation. There is a separate article on each book of the Bible and standard Apocrypha, and other books are discussed in APOCRYPHA, NEW TESTAMENT and APOCRYPHA, OLD TESTAMENT. Some of the major groups of biblical books are described in, *e.g.*, GOSPELS; PENTATEUCH; PROPHET. Early Christian writings are the subject of the articles APOLOGISTS, EARLY CHRISTIAN and APOSTOLIC FATHERS. There are articles on many subjects of interest to Old Testament studies (*e.g.*, DEAD SEA SCROLLS; ISRAEL; ZION), archaeological sites (*e.g.*, CARCHEMISH; ERECH; LACHISH), peoples and geographical regions (*e.g.*, CANAAN; EDOM; KENITES), significant biblical figures (*e.g.*, DAVID; JUDAS ISCARIOT; MOSES; PAUL, SAINT), and specific biblical topics (*e.g.*, ARK; BEATITUDES; DECALOGUE; LORD'S PRAYER; SERMON ON THE MOUNT).

Other.—THEOLOGY, CHRISTIAN is the leading article on that subject, with major articles also on FAITH; FUNDAMENTALISM; LIBERALISM, THEOLOGICAL; MYSTICISM; NEO-ORTHODOXY; ORTHODOXY, PROTESTANT; etc. ATONEMENT; GRACE; INSPIRATION; REDEMPTION and other similar articles deal with basic elements of Christian theology. MINISTRY, CHRISTIAN; EPISCOPACY; CLERGY; HOLY ORDERS; and ORDINATION are among the articles concerned with the clergy. Other ecclesiastical offices are discussed in (among others) ACOLYTE; ARCHDEACON; DEACON; DEACONESS; DEAN. VESTMENTS, ECCLESIASTICAL outlines the history and use of, and describes, Christian and Jewish vestments. Besides SACRAMENT, there are several articles concerned with the sacraments individually, especially EUCHARIST and BAPTISM, CHRISTIAN.

CHURCH YEAR outlines the Christian liturgical year and provides cross references to separate articles on the important feasts and seasons. Further information about Christian worship is provided in LITURGY; MASS; HYMN; and PREACHING. CATECHISM; CREED; and CONFESSIONS OF FAITH, PROTESTANT (along with many separate entries on catechisms and confessions) are concerned with Christian statements of belief. MISSIONS gives the history of Christian evangelistic work.

WORLD COUNCIL OF CHURCHES, THE and ECUMENICAL MOVEMENT deal with modern church reunion activities. NATIONAL COUNCIL OF CHURCHES and FREE CHURCH FEDERAL COUNCIL describe two important interdenominational co-operative bodies. CONVOCATIONS OF CANTERBURY AND YORK; CHURCH COMMISSIONERS; and ECCLESIASTICAL LAW (ENGLISH) have to do with the government and administration of the Church of England.

Ideas of God.—These are discussed especially in DEISM, PANTHEISM and THEISM, as well as AGNOSTICISM and ATHEISM. YAHWEH is concerned with the ancient Hebrew conception of God; BRAHMA AND BRAHMAN with that of the Hindus; and ALLAH with that of the Muslims. DEVIL and SATAN deal with the concept of personified evil in religious systems. DUALISM treats of those systems that postulate the coexistence of two opposite and irreconcilable forces.

Other Religions.—The great non-Judaeo-Christian religions of the world today are dealt with in BUDDHISM; CONFUCIANISM (which, while not strictly a religion, is religious in its philosophy and its promotion of traditional rites); HINDUISM; ISLAM; TAOISM. In addition, there are articles on the major branches of these (*e.g.*, for Islam, ISMA'ILISM, KHARIJITES, SHI'ISM, and SUFISM; for Hinduism, SHAKTISM, SHIVAISM, and VISHNUISM; for Buddhism, TIBETAN BUDDHISM and ZEN). Other religions, existing but less widespread, are the concern of BAHA'I FAITH; DRUZE; JAINISM; PARSEES; SHINTŌ; SIKHISM. Great religious systems of the past are discussed in BABYLONIA AND ASSYRIA: *Religion;* EGYPT: *History: Ancient Religion;* GREEK RELIGION; MANICHAEISM; MITHRAISM; MYSTERY; ROMAN RELIGION; VEDIC RELIGION; ZOROASTRIANISM; etc. GRANTH; HADITH; JATAKA; KOJIKI; KORAN; MILINDAPANHA; NIHONGI; and SANSKRIT LITERATURE (for Hinduism) are among the numerous articles on sacred scriptures. There are separate articles on the major deities of the polytheistic religions.

Among articles on subjects of concern to nearly all religions are CREATION, MYTHS OF; ESCHATOLOGY; HEAVEN; HELL; MYTH; PRAYER; FEAST AND FESTIVAL; PRIESTHOOD; SACRIFICE.

Primitive Religion.—The basic article is RELIGION, PRIMITIVE. Among other articles concerned with aspects of religion commonly called primitive are: ANCESTOR WORSHIP; ANIMAL WORSHIP; ANIMISM; FETISHISM; HUMAN SACRIFICE; MAGIC, PRIMITIVE; PASSAGE RITES; SHAMANISM; and TOTEMISM.

More or less organized "primitive" religions are discussed in CARGO CULTS; GHOST DANCE; NATIVISTIC MOVEMENTS; PEYOTISM; SECRET SOCIETIES, PRIMITIVE; SUN DANCE; and VOODOO.

RELIGION, man's relation to that which he regards as holy. The "holy" need not be thought of as supernatural, much less as personal; and if the word "god" be defined in personal or supernatural terms, it follows that religion includes far more than the relation to God or a god. Similarly, the term "relation" to the holy may be conceived of in a variety of forms. Worship (*q.v.*) is probably the most basic of these, but moral conduct, right belief, and participation in religious institutions are generally also constituent elements of the religious life as practised by believers and worshipers and as commanded by religious sages and scriptures.

An outline and summary of information about religion appears in RELIGION (ARTICLES ON). Particular religions are treated in separate articles, such as BUDDHISM, CHRISTIANITY, CONFUCIANISM, HINDUISM, ISLAM, JUDAISM, and the like. RELIGION, PRIMITIVE deals with religious phenomena, especially as they concern primitive cultures. The present article is concerned merely with the definition and description of religion as a characteristic of human life.

Man, it has been said, is incurably religious. This is an epigrammatic and slightly facetious statement of the most impressive feature of religions, viz., their wide distribution. All through human history as we know it and all through present-day societies as we know them, there appears some such relation to what is regarded as holy. To cover all these phenomena, however, the definition of religion must be so comprehensive as to become ambiguous, if not even meaningless. The very etymology of the word suggests this ambiguity. Since ancient times there has been discussion of whether "religion" comes from *relegere,* "to read again," or from *religare,* "to bind." Each successive broadening of man's physical horizon through exploration and discovery, moreover, has necessitated a redefinition of religion to include unfamiliar phenomena and to exclude features that had been part of the older definition because of a generalization based on acquaintance with too few forms of the religious life.

Thus the experience of Western men with primitive societies during the 16th and 17th centuries brought about a reconsideration of what had been thought to be the content of the natural law, the irreducible minimum of moral precepts common to all men. Western confrontations with Confucianism and with certain forms of Buddhism made it clear that theism (*q.v.*) as traditionally understood in the West is by no means a universal tenet among the world religions. During the latter part of the 19th century, therefore, students of world religions were beginning to despair of finding any universals at all. In 1917 Rudolf Otto (*q.v.*) introduced the category of "the holy" as a possible universal. Although Otto's interpretation of the category did not satisfy everyone, the category itself did gain wide acceptance as a designation for the distinctive content of religious feeling. Admittedly, Otto, who was intent upon making a case for the autonomy of religion, slighted both its communal character and its diffusion throughout a culture. Nevertheless, every religion has at least some of these elements: rituals to perform, formulas to recite, tales to narrate, objects to manipulate, places to frequent or avoid, holy days to keep, natural phenomena by which to predict the future, charismatic leaders to follow, truths to affirm, a literature to ponder, precepts to obey. Vary though they undoubtedly do in content, most of these elements are sacred to most religions, and the study of religion must consider all of them—and more.

To be religious, then, is to be related to the holy in one or more of these ways. Probably the most nearly universal among them, as suggested above, is worship, if such activities as prayer, sacrifice, contemplation, magic, and incantation are included in that term. Primitive religion is replete with instances of traditions in which there is little or no doctrine as such but many prescriptions of proper ritual. Ancient Roman official religious observance was separate from personal commitment and private morality in ways that adherents of Judaism and Christianity have found incomprehensible. If worship is obligatory, there must be a right way and a wrong way to perform it; a mistake in religious language or sacred gesture may invalidate the worship or jeopardize its effectiveness for petition, atonement, or thanksgiving. Failure to prepare adequately through fasting, etc., may profane the observance. Worship is frequently tied to specific times and locations, to holidays and festivals, seedtime and harvest, puberty and marriage, birth and death. The religious leader is commonly the functionary in worship, be he priest or shaman or medicine man (*see* PRIESTHOOD; SHAMANISM). When a religion traces its origin to a founder, he is often credited with having established and prescribed the proper forms of worship or sometimes with having purified traditional forms. The fundamental place of worship in religion is evident also in its durability: men may continue going through the motions of religion long after they have transferred their personal loyalty and trust to objects other than those of the traditional observance.

Closely associated with worship is conduct. Though it is possible to separate ritual observance from moral conduct, worship has so generally implied "being right with" the object of worship that in widely separated religions the religious man has been thought of as the one who followed a certain way of life. (In Western Christian usage, indeed, "religious" came to be synonymous with "monastic," in the sense of being bound by a vow to the observance of the way of life prescribed by a particular community.) Thus Buddhism developed its Noble Eightfold Path, Judaism its Ten Commandments, Parseeism its requirement of charitable acts. In the course of its history a religion has often been obliged to reinterpret its ancient moral commandments in the light of new experiences or unforeseen problems. Many of the most bitter controversies in the history of religions have been fought by strict constructionists who adhered to traditional prescriptions and by revisionists who sought to adapt both moral and ceremonial requirements to the changing situation. At times, interpreters of religion have virtually equated all of religion with its moral imperatives, reducing its other constituents to supports for the ethical. Eventually any such reduction has demonstrated its own inadequacy as a description of the full scope and the profound subtleties of the religious experience of individuals and communities. Even this reductionism indicates the crucial role of the moral consciousness in the determination of man's relation to what he regards as holy. (*See* also ETHICS, COMPARATIVE.)

Among scholarly interpreters of religion in the West, where the "science of religion" (German *Religionswissenschaft*) began, the Christian preoccupation with dogma (*q.v.*) has helped stimulate a concentration on comparisons between the teachings of the various religions about God, man, creation, sin, immortality, etc. An important outcome of this concentration has been the collection and translation of Oriental scriptures in such multivolume sets as *The Sacred Books of the East,* edited in 51 volumes by F. Max Müller, a pioneer in comparative philology and in the comparative study of religion. Religions that lack scriptures in the formal sense are usually endowed with mythology, in which some scholars have claimed to be able to discern a primordial form of doctrinal belief (*see* MYTH). To students of non-Western religion who have approached Oriental scriptures and myths without this theological predilection, the comparison of doctrines has often appeared to be an artificial superimposition of alien Western categories on the material and too one-sidedly cerebral account of the meaning in religious language and action. In reaction against the method of the comparative study of doctrine, historians of religion have preferred to investigate each religion on its own terms, leaving comparison to a later stage of research and reflection. Nevertheless, the practice of a religious cult or the recitation of a myth does seem to imply at least that what is being enacted or affirmed is a revelation of divine truth, whether literal or symbolic. And at some stage in the development of many religions, such implied beliefs have been brought to the level of explicit statement and critical examination and thus to the status of doctrine.

The theological, literary, and philosophical orientations of earlier generations of scholars gave way, during the 20th century, to the growing dominance of the new methods of the social sciences, especially those of anthropology, sociology, and psychology. The fundamental insights of these disciplines into the place of religion within the total life of man have significantly affected the interpretation of religious phenomena, including the interpretation underlying the present article. This shift of emphasis has rendered such ideas as Otto's definition of the autonomy of religion extremely questionable, but it has also directed attention away from the almost exclusive concern with the individual and his beliefs and experiences to the social function of religion in a family, a tribe, or a culture. William James said that religion is the "experiences of individual men in their solitude"; Émile Durkheim maintained that religion is "essentially social." The social embodiment of religion in corporate activities and institutions became the centre of interest. Religion thus became a matter of one's membership and participation in those activities and institutions, not simply in the sense of being a "joiner" but in the sense of finding one's own identity and that of one's group in the structures of the religious tradition, which hallow, celebrate, and judge the entire culture. When this social dimension is included in the definition and study of religion, the other aspects come into a new perspective and into new connections with one another; for example, myth and ritual illuminate each other when both are seen in their corporate context.

As the interest of the social sciences in religious phenomena proves, religion is too important to be left solely to interpretation by philosophers, theologians, and religionists. Several explanations of religion by thinkers in other fields are sufficiently widespread to warrant mention in even so brief an article as this. Many historians have tended to see religion as a sort of primitive science, as, for example, astrology preceded astronomy; religion is then interpreted as an attempt to explain by means of symbols what empirical scientific study describes in the nonaffective language of precise measurement. The familiar remark of Karl Marx that religion is "the opium of the people" was an expression of his observation that "religion is the sigh of the oppressed creature, the feelings of a heartless world." Sigmund Freud redefined the nature of religion in the light of his theories about human nature and development, concluding that in religion God "really is the father, clothed in the grandeur in which he once appeared to the small child. . . . [One] therefore looks back to the memory-image

of the overrated father of his childhood, exalts it into a deity, and brings it into the present and into reality." Carl Jung revised Freud's theories in the direction of discovering and tracing the symbols and "archetypes" in which men, individually and collectively, find explanations for the mystery and meaning of their lives. These and other analyses of the data of religion suggest that man's relation to that which he regards as holy, as that relation is expressed in ritual, in ethics, in belief, and in institutions, continues to be a matter of interest both to those who profess a religious faith and to those who profess to have none.

RELIGION, PRIMITIVE. "Primitive religion" as a descriptive and qualitative definition of the early forms of man's religious life took its place in the vocabulary of the history of religions and anthropology as a result of the work of two great scholars, Sir E. B. Tylor and Sir James Frazer. The work of both reflects the desire that motivated much of the early research into the phenomena of primitive religion: to understand the origin of religion in human history. "Origin" was understood in at least two senses: as the beginning, the first or earliest form of religion, and as the basic, elementary form of religion.

To Tylor's "minimum definition" of religion as "the belief in spiritual beings" many objections have been raised because of its incompleteness. It does not include ritual or ceremony, and Tylor's notion of "spiritual being" does not cover adequately the relationship between the spiritual and material or quasi-material realities that are prevalent in primitive religions. Frazer, in *The Golden Bough,* seems to supplement Tylor when he proposes the definition of religion as "a propitiation or conciliation of powers superior to man which are believed to direct and control the course of nature and of human life." He explains further: "Thus defined, religion consists of two elements, a theoretical and a practical, namely, a belief in powers higher than man and an attempt to propitiate or please them."

Frazer's definition seems to include religious expression as well as attitude. Nonetheless, he has some difficulty in separating religion from magic when he deals with empirical expressions, though he makes a very precise theoretical distinction between the two. By "powers" he means "conscious or personal agents." Magic practice assumes that the course of nature is determined "by the operation of immutable laws acting mechanically." On the contrary, religious belief and practice assumes that the course of nature is elastic or variable and that the conscious beings who control it can change its course for the benefit of the worshiper. Frazer believed that magic constituted a stage of development prior to the advent of religion. (*See* further MAGIC, PRIMITIVE; PRAYER.)

Frazer's difficulty in disentangling the magical from the religious points to one of the major objections to his general orientation as well as to that of Tylor. Both, by emphasizing belief as the most important element in the religious attitude, are hard put to deal with the many practices, rites, and ceremonies which, though closely related to belief, cannot be adequately understood as arising directly from it. Tylor explained these phenomena as the result of a mistaken association of ideas among primitive peoples; Frazer relegated them to the arena of magic. Their definitions of religion, therefore, are to be accepted, if at all, as definitions of type, selective designations of some features of primitive religion, but not universally applicable.

Objections have also been raised to the philosophical and historical implications in the theories of Tylor and Frazer. Their assumption that the mind of primitive man is illogical and confused, or that its operations are radically different from those of other men, is no longer held to be true by the majority of anthropologists and historians of religion. The further assumption that present-day primitive peoples have no history has been conclusively disproved.

The argument for continued use of the term "primitive religion" thus must be made on the grounds of practicality alone—an acceptable replacement has not been found. In the article below, "primitive" will be taken to have reference to those cultures that are prior in time to the advent of the large cultural complexes called civilizations or that, though contemporary with, have not been decisively affected by "civilization."

To take account of the great mass of data in these cultures, a more comprehensive definition of religion is also needed. Such a definition is suggested by E. Crawley in *The Tree of Life,* where he points out that "neither the Greek nor the Latin language has any comprehensive term for religion, except in the one *hiera* and in the other *sacra,* words which are equivalent to 'sacred.' No other term covers the whole of religious phenomena, and . . . no other conception will comprise the whole body of religious facts." An important consequence of thus giving the study of primitive religion the wide scope of comparative hierophany is that magic no longer must be divorced from religion, since the sacred will now be found coextensive with the magico-religious. Rudolf Otto concurs with this sentiment: "*Religion is itself present at its commencement:* religion, nothing else, is at work in these early stages of mythic and daemonic experience" (*The Idea of the Holy,* Eng. trans., 2nd ed., p. 132; London: Oxford University Press, 1950). A similar judgment is expressed by Mircea Eliade when he admits that any attempt at a definition of religion must look for the evidence, and, "first and foremost, for those expressions of religion that can be seen in the 'pure state'—that is, those which are 'simple' and as close as possible to their origins." Eliade counters this proposal, however, by the recognition that "Unfortunately, evidence of this sort is nowhere to be found; neither in any society whose history we know, nor among 'primitives,' the uncivilized peoples of to-day." (From *Patterns in Comparative Religion* by Mircea Eliade, © Sheed & Ward Inc., 1958.)

MANIFESTATIONS OF THE SACRED

The manifestation of the sacred is related on the one hand to the particular cultural historical period in which it is apprehended, on the other hand to the specific phenomena through which it makes itself known. Specific religious symbols therefore tend to dominate in specific historical periods and cultural areas.

Myth and ritual constitute the general and almost universal forms of religious response. In the myth, the story of a manifestation of sacredness is related, understood to be a "true story"—*i.e.,* a story of the appearance of that reality which makes it possible for man to understand his world as real (*see* MYTH). It is therefore the basis for the world view, and it provides the pattern for man's orientation and relationship to all the other data of his experience. While a society may relate several types of myths—magical, cultic, etiological—the myth par excellence is the cosmogonic myth, the story of the first creation, which becomes the prototype for all other myths within a society. Often the myth is related to a ritual, the forms of which enable the worshiper to reenact the story. But "myth" should not be restricted to its ritual use or meaning. It is a specific type of perception and response to reality that has religious implications beyond its dramatization in ritual.

The Sacred in Nature.—G. van der Leeuw (*Religion in Essence and Manifestation*) showed that religion did not rise from a "worship of nature" but from the sacred reality in nature. The "manifestation of the sacred in nature" refers to the manner in which animals, plants, the sky, and the landscape reveal modalities of reality to man. Though these phenomena often have utilitarian meaning, this does not explain the religious veneration which is a part of the technique of dealing with them.

The oldest gods in most cultures are sky-gods. The sky expresses that which is eternal, infinite, and transcendent. When it becomes sacralized it becomes a revelation of the power of divine activity. The presence of sky-gods in most primitive religious systems led

Wilhelm Schmidt (*q.v.*) and the "Vienna school" of ethnology to infer a primitive monotheism. But though many primitive religions recognize their existence, sky-gods are, for the most part, *dei otiosi*. They seem to have retired from any direct influence on man, their places being taken by new sacred manifestations. They are called upon only in the most crucial situations and then with great fear and trembling.

Animals constitute another aspect of nature through which, apparently from very ancient times, the sacred has made itself known among primitive peoples. Evidence from prehistoric sites ranging from early Paleolithic through Neolithic times indicates a special veneration of animals. Finds of the early Paleolithic period in western Europe yield a large number of bear skeletons, suggesting that some magico-religious practices may have been involved in the hunting and eating of this animal. Johannes Maringer (*The Gods of Prehistoric Man*) thinks that some elements of an early bear cult remain in the ceremonies of modern primitive peoples of the circumpolar regions, where the bear enjoys special veneration.

Animals are the primary subject of the late Paleolithic cave art that may be found all over western Europe and eastward as far as Siberia and southward to northern Africa (*see* PRIMITIVE ART: *Prehistoric Europe*). These paintings represent animals, usually reindeer or antelope, sometimes in herds, sometimes singly, often the victims of hunters' arrows. It is possible to understand this art as part of a magico-religious complex bound up with the hunting culture. Though it is of course impossible to make any firm assertions about the thoughts of prehistoric peoples, it seems safe to say that the cave paintings probably were intended to make the game animal more accessible to the hunter and may also have expressed an identification of the hunter with the animal. In the cave of Les Trois Frères at Montesquieu Avantès (Ariège) the famous painting of the sorcerer shows a figure with a long beard, the eyes of an owl, the antlers of a stag, the ears of a wolf, the claws of a lion, and the tail of a horse—a composite of several animals that can hardly be explained except in religious terms.

Understanding of prehistoric man, knowledge of whom is entirely dependent on archaeological finds, may be supplemented at least inferentially by studying forms similar to the prehistoric among modern primitives. Among these, the phenomenon of totemism is instructive. It exhibits two primary features: (1) the existence of a human group is inextricably bound up with a particular animal (the totem); and (2) various tabus surround the totem. Totemism—and likewise, it may be inferred, the cave art of prehistoric man—represents a recognition that there is sacred power in the animal and that man's life is materially and spiritually linked with its life. (*See* further TOTEMISM.)

The Sacred in Plants.—The life of plants presents another important level of nature through which the sacred makes itself known. The Paleolithic hunting cultures, it is suggested, apprehended the sacred within a magico-religious complex emphasizing the wild animal. Man's discovery of agriculture (*see* AGRICULTURE: *World Agriculture: Origins of Agriculture*) produced a new structure of the sacred, the power of which now came to exhibit itself in the life of plants and to take the form of fertility, in plants and in the life of man. Within this religious structure the suffering god (Adonis, Attis, Osiris, as Frazer showed, but there were others as well) also appears: for if the sacred is homologized to the life of plants, then representatives of the sacred power must undergo death and resurrection.

With the domestication of animals, a new veneration of certain forms of animal life also was produced, and the bull, a symbol of fecundity, appears with the various symbols of the mother-goddess in religious rituals involving sacred marriage.

It must be emphasized that the natural phenomenon of agriculture is not responsible in itself for this new religious orientation; rather it is the religious experience apprehended within the context of the "new world" created by the advent of agriculture. This religious structure may be traced throughout the history of the world's cultures from the time of the agricultural revolution. Among modern primitives traces still remain. The cosmic duality of sky and earth, found today in Africa, America, and Oceania, demonstrates how the old sky-gods, with the discovery of the sacred in the life of plants, took on the new religious structure involving sexuality and fertility. The earth, in the form of a mother goddess, now becomes the creator and sacred ground of all beings. This discovery, coupled with the sedentary character of life made possible by agriculture, gave rise also to the veneration of geographical places.

Sacred Representations in Man.—Man is both repelled and attracted by the manifestation of the sacred. Attracted, he wishes to participate more fully in the power revealed. In modern primitive societies a number of forms of human bearers of power, who act as mediators of the sacred to the entire community, may be catalogued, but the most pervasive are the king or chief and the medicine man or shaman.

The king or chief in primitive society holds hereditary office, his lineage usually extending back into the mythological past and his oldest ancestor usually being identified with the first man. The king represents the power that gives reality to the existence of the society, and he is therefore responsible if a catastrophe occurs, if the crops are bad. His person and all persons or objects related to him are sacred and hedged in by tabus. (*See* further KING: *Theory of the Divine King.*)

The king possesses his office not because he is a religious virtuoso but because of his lineage. The other important human representation of the sacred is based on the representative's personal religious experience. The medicine man or shaman is a manipulator of power, to which he claims direct access either through divination or through a specific type of religious experience of which only he is capable. Among Eskimos, American Indians, and Siberians, the shaman's power rivals that of the chief. (*See* further SHAMANISM; PRIESTHOOD.)

The Sacred in Community.—The avenues of sacred power issuing in kings, shamans, and medicine men are open only to the "elect." But the ordinary man in the primitive community also apprehends the sacred realities within the important events of the common life, the events called by Arnold van Gennep the transitional rites (*rites de passage*), including birth, initiation, naming, the outbreak of war, and death and burial. All these events represent periodic irruptions of sacred power within the community, and appropriate ceremonies always accompany them. With the possible exception of the ceremony accompanying the outbreak of war, all the transitional rites are initiatory—that is, they reveal to the novice a new, sometimes esoteric meaning of the sacred. Every birth is a paradigm of the birth of the first man and the sacred life given to him by the gods. In puberty rites, the mystery of sexuality is revealed; the novice assumes his role as a man and is given a name. In death and burial rites, the community prepares man for the mysteries of the afterlife. Among many primitive peoples life may almost be described as a continuous initiation. (*See* further PASSAGE RITES.)

Outside ceremonial activities, religion plays an important role in the ordering of primitive societies. Religious groups may be coterminous with natural groups, or they may be created by specific religious experience. Where the religious group is coterminous with the family, as is common in West Africa, there is usually a family cult with a member of the family as cult leader. The most prevalent form of specifically religious group in primitive culture, however, is the secret society, founded on a new, esoteric revelation of the sacred to the initiated. (*See* also SECRET SOCIETIES, PRIMITIVE.) Religion thus may be seen as one of the primary factors affecting social differentiation in primitive societies.

ASPECTS OF THE SACRED

Though in primitive religion varieties of gods, tricksters, malevolent beings, fetishes, and magico-religious practices are met with, the comprehensive reality is the reality of the sacred, the reality defined by Otto as "the holy." The religious attitude engendered by the encounter with this reality is "numinous," which may be analyzed into two dialectical feelings: the *mysterium tremendum*, the element of awe and dread; and the *mysterium fascinans*, the feeling of fascination, wonder, and attraction. (*See* also OTTO, RUDOLF.) It is possible, however, to analyze the sacred

into more specific categories, outlined below.

The Sacred as Powerful.—The sacred always manifests itself as power, as seen in the notion of *mana* among the Melanesians (*see* MANA) and in similar conceptions, such as the *orenda* of the Iroquois and *wakanda* of the Sioux. Though *mana* is often understood to be impersonal—in the sense of its arbitrariness—it always manifests itself in some person or thing, endowing that person or thing with the efficacious power that resides in the sacred. This power is often identified as the "vital" or life force in all living things. Among the Melanesians *mana* may refer to influence, strength, fame, or anything regarded as extraordinary. However, men and things possess this power only because it has been given to them by more powerful beings.

The Sacred as Dangerous.—The sacred is dangerous because it is powerful. This character is expressed by the Polynesian term *tabu,* meaning that limits are set about the sacred person or object (*see* TABU). Among primitive people all ceremonial activity, the sexual life, the person of king or chief, and certain times and seasons bring into operation an elaborate set of tabus which give recognition to the sacred power manifested in these dimensions of man's existence.

The Sacred as Mystery.—The sacred is mysterious because it is the manifestation of that which is extraordinary, that which cannot be known by ordinary means. Religious knowledge is revealed by the manifestation of the sacred in a specific form to a specific person or people. The totem animal of the Australians, though commonplace in the Australian environment, is at the same time uncanny and unique. It is mysterious precisely because its relation to the totem group is more than a pragmatic economic relationship.

The Sacred as Secret.—Closely related is the notion that the sacred is secret. The literal sense of the term *churinga,* applied by the central Australians to their sacred objects and likewise used more abstractly to denote mystic power (as when a man is said to be "full of *churinga*"), is "secret." This is symptomatic of the esotericism that is a striking mark of Australian and indeed of all primitive religion, with its insistence on initiation and its strictly enforced reticence concerning traditional lore and proceedings. The religious system of a particular tribe may be based on a sacred tribal secret; more esoteric secrets are known by smaller groups within the tribe. There are secrets that are known only by men, others known only by particular groups of men, others known only by those who follow a certain occupation.

THE MEANING OF THE SACRED IN PRIMITIVE SOCIETY

The esoteric character of many of the forms and practices of primitive man has led some scholars to attribute them to a "prelogical mentality," unable to think rationally about the meaning of existence. Lucien Lévy-Bruhl, who originated this interpretation, understood primitive man to employ a "law of mystical participation": primitive man did not recognize the subject-object distinction as a basis for knowledge, but sought knowledge through identifying himself mystically with the phenomenon to be understood. Bronislaw Malinowski, on the other hand, attempted to show that primitive man is able to think rationally and that he employs different modes of thought in dealing respectively with the dimensions of life defined by magic, science, and religion. Though he affirmed the similar functioning of the human mind at all cultural levels, he finally interpreted religion as a necessary, important, but fictional dimension of culture.

Émile Durkheim, in *Elementary Forms of the Religious Life,* introduced the notion of religious symbolism as an interpretation of religious expression. The emphasis on symbolism is important, but by referring it only to the social group Durkheim fails to explain its many other meanings and referents. The religious life of primitives cannot be explained simply in terms of the social group nor by recourse to a theory of prelogical or nonrational mentality. Through the religious symbol a variety of phenomena are ordered to express the quality of ultimacy and absoluteness in the world of man. It reveals a perception of the world different from the ordinary level of experience. Primitive man, understanding the sacred as the real, orients himself toward and participates in this reality through rites and ceremonies. In more highly developed religious systems the expressions are different, but the intent seems to be the same.

In religion man feels that he is in contact with ultimate reality, the power of which has created and continues to support his being. This reality is not apprehended in a general way but is mediated through specific forms and structures. The primary religious symbols of primitive societies define the "world" for the members of the society. Thus the specific symbols of the sacred refer not only to the manifestation of the sacred, or to the social group, but also to the peculiar "existential" stance man assumes in his world. Involved in the notion of the sacred in primitive societies is a complex of ideas—cosmological systems, ideas of time and space, social order, etc. Since the sacred defines the real, all important realities of life participate in the sacred. The pre-eminence of religion and religious symbolism in primitive societies confirms this observation.

RELIGIOUS ARCHITECTURE. This article is concerned with the development of Western religious architecture in the 20th century. After a brief introductory account, the countries that have contributed most to this development are examined. For earlier religious architecture of the Western world, *see:* BYZANTINE ARCHITECTURE; ROMANESQUE ARCHITECTURE; GOTHIC ARCHITECTURE; RENAISSANCE ARCHITECTURE; BAROQUE AND POST-BAROQUE ARCHITECTURE; MODERN ARCHITECTURE. For the religious architecture of other parts of the world, *see* appropriate headings; *e.g.,*

CHINESE ARCHITECTURE; IBERO-AMERICAN ARCHITECTURE; INDIAN ARCHITECTURE; ISLAMIC ARCHITECTURE. *See* also PAGODA; TEMPLE ARCHITECTURE.

Historical Background.—When Constantine recognized Christianity by the Edict of Milan in A.D. 313 a pattern of church architecture as such did not exist. The earliest Christians had worshiped in the houses of wealthier members or in the catacombs, which in Rome were particularly extensive. A converted house in Doura-Europus in eastern Syria is held to be the first-known Christian church, dating from 232. In both the Eastern and Western halves of the Roman Empire, however, a certain amount of uncoordinated church building took place.

As Christianity became established throughout the Roman Empire a building type for sheltering a large congregation evolved from the basilica (*q.v.*), found in Rome and Roman North Africa. This was a sizable rectangular building the interior of which was divided by two rows of columns into a large central hall with side aisles. It was easily roofed in wood. By putting the altar at one end, preferably in a niche with space for suitable circulation in front, and by locating the entrance at the opposite end, a basic church pattern was established. The basilica-inspired old St. Peter's in Rome, which Constantine built in *c.* 326 and which was substantially replaced by the present St. Peter's in the 16th century, was one of the first of these. The same plan was used later in the 4th century in Rome in S. Clemente, Sta. Maria Maggiore, St. John Lateran and St. Paul's Outside the Walls, to name only the finest extant examples. The long basilica nave was suited to church processionals and produced a stunning spatial impression as well. At the sanctuary end was a slightly raised platform, or bema, with a semicircular apse, often gloriously covered with mosaics, directly behind.

In the formative days of the Christian Church, however, plans other than the basilica were used. The circular church and baptistery, undoubtedly inspired by Greek and Roman temples and tombs, were common. S. Stefano Rotondo in Rome (*c.* 475) is the largest and best known of these. In the 6th century the Byzantines explored an even more complex geometry. SS. Sergius and Bacchus in Constantinople (523–527) is a domed octagon enclosed in a square, while its contemporary, the sublime Hagia Sophia, is square outside, domed and counterdomed within. Charlemagne's mausoleum chapel at Aachen (796–804) has 16 sides. The opulent St. Mark's in Venice, finished in 1073, has four arms of equal length, making a Greek cross. The geometry that characterized church planning until the beginning of the Romanesque had, thus, an ingenious variety.

From the fall of Rome in A.D. 476 to the Romanesque beginnings around 1000, little building of any type was done in Europe with the exception of the Byzantine work centred around Ravenna and Venice. Then came the golden age of church building in Western Europe. This began in the 11th century with the Romanesque style, reached its religious peak with the Gothic during the 12th to 15th centuries (varying in different countries), and continued in a more elegant but less spiritual form in the Renaissance of the 15th and 16th centuries. It is significant that almost all of these were adaptations of the long-armed Latin cross in plan. Indeed it is this Latin plan, largely as developed in the Middle Ages, which determined church planning, both Roman Catholic and Protestant, until modern times.

During the late Renaissance and continuing with the Baroque and Rococo periods down to the 17th and 18th centuries, however, a revolt against the rigid Latin-cross plan occurred, particularly in Italy and southern Germany where a number of extremely interesting, more centrally planned churches evolved. These churches were not only less "authoritarian"; they sought a more intimate atmosphere, and it is pertinent to note that many of these flowing geometric shapes were revived in modern German churches. But after the late 18th century and particularly during the age of architectural revivals from the 19th century onward, the familiar Latin plan again dominated church design.

20th-Century Developments.—Beginning in the early 20th century, when architects everywhere increasingly questioned the copybook styles that had stultified building for almost 200 years, a new freshness was evident. This was primarily the result of two factors: a reassessment of the basic relationship between clergy and congregation; and revolutionary new materials of steel and reinforced concrete, both of which were introduced in the mid-19th century.

The long nave of the Latin cross isolates much of the congregation from the priest or minister and the sanctuary. Not only is it difficult to hear the sermon throughout many attenuated churches —as the presence of amplifying systems testifies—it is also difficult to feel in touch with the altar and sanctuary. As church processionals largely disappeared, virtually altogether in Protestant churches, the liturgical necessity for a long nave likewise diminished. As a result a more compact planning, evolving toward a one-room ambiance and designed to bring clergy and congregation closer together, became evident. The customarily precise divisions of nave, transept, chancel, and sanctuary gave way to a more open and intimate interior. Enhanced by the overall developments of 20th-century architecture, a general simplification and unity in church architecture of all faiths evolved.

Although the changes in liturgical relationships brought obvious changes to the appearance of modern churches, even greater changes occurred through the use of new materials, such as reinforced concrete, steel, processed (*i.e.*, laminated) wood, and new forms of glass.

Concrete had been used in churches since the end of the 19th century, notably by Anatole de Baudot in his Saint-Jean de Montmartre in Paris (1894), but always as a structural means within a largely stylistic framework. It was not until 1923 that reinforced concrete was fully used and expressed in a church (Notre Dame, in Le Raincy, a suburb of Paris; Auguste and Gustave Perret, architects).

The first steel and glass church, the Stahlkirche, was built by Otto Bartning in Cologne in 1928. Modeled to a large extent after the famous 13th-century Sainte-Chapelle in Paris, this church, later destroyed, had a maximum amount of stained glass and a minimum of structure.

Industrialized or processed wood was another new material that markedly affected the structural design of 20th-century churches. New forms and uses were given to man's most venerable building material. Church architects, especially in the United States, made frequent use of prefabricated laminated wood arches which became readily available. Handsome and economical, wood has a visual and tactile warmth, plus excellent acoustic qualities, which make it well suited for religious work.

Another old material in new guise that had a stimulating role in 20th-century religious architecture is a glass technique called *Betonglas* (*i.e.*, "concrete glass") or mosaic glass. It is made from faceted bits of brilliantly coloured glass, approximately an inch thick. Instead of the various sections being supported and separated by lead dividers, as in stained glass (*q.v.*), the thick glass chunks are laid and composed, like a mosaic, on the flat, with wire reinforcing rods laced between and fine concrete poured in the interstices. When the concrete has set the panel is polished; it then forms a self-supporting, weatherproof unit ready to be raised in place. *Betonglas* has a depth and richness, a glowing quality, which is almost jewellike in its changing intensities. It became popular in France, where it first evolved in the late 1920s and early 1930s, and its use spread to much of the continent and to North and South America. One of its most impressive single installations is in Wallace Harrison's First Presbyterian Church (1958) in Stamford, Conn.

France.—France, which gave birth to the Gothic style and took it to its greatest heights, was also responsible for establishing the 19th-century Classic revival both in architecture and in art. The extraordinary archaeological discoveries of the late 18th century (particularly J. J. Winckelmann's work in Greece) and Napoleon's imperial leanings set the stage for this Neoclassical idiom. The search for ancient prototypes was far more of an architectural atavism at this time than it had been during the Renaissance. Renaissance architects sought inspiration in the glories of Greece and Rome; the Neoclassicists sought ancient models, or authentic ancient elements for new buildings. The movement was epito-

mized in France by Napoleon's *temple de la Gloire,* the Madeleine (1806), by Pierre Vignon.

Pleasure in the Neoclassical style in France, as elsewhere, waned, however, and toward the middle of the 19th century interest revived in the Gothic. E. E. Viollet-le-Duc was the continent's chief champion of the Gothic revival and his *Dictionnaire raisonné de l'architecture française* (1854–68), along with his many restorations, including that of Sainte-Chapelle, sparked wide enthusiasm throughout Europe. In France more neo-Gothic restoration—in some cases violation—was executed than new construction, but several prominent churches were built, such as: Sainte-Clotilde in Paris by F. C. Gau and T. Ballu (begun in 1846); Saint-Nicolas in Nantes by L. A. Piel and J. B. A. Lassus (1854–59); and Saint-Epvre in Nancy (1864–79), by M. P. Morey.

Following the Gothic revival, architectural uncertainties for almost a century resulted in a combination of styles. The most prominent Parisian example of this period is the Sacré Coeur, begun in 1875 by Paul Abadie and continued by Pierre Daumet and L. Magne. The Neoclassical and neo-Gothic had a certain "authenticity," although generally cold and lifeless, but the church architecture that followed in France and elsewhere until after World War I was almost totally undistinguished.

When the Perrets built their Notre Dame du Raincy in 1923, using reinforced concrete, they established a milestone in the rejuvenation of Christian church architecture. The roof is supported by slender concrete columns; the outside walls are pierced panels of concrete, each panel being laced with a series of geometric openings in which are set panes of coloured glass. The interior effect of this small church (it measures only 184 × 66 ft.) is one of reverent simplicity and timeless grace. It has few equals.

The effect of Notre Dame du Raincy permeated all Europe. The Perrets themselves built Sainte-Thérèse, a somewhat similar church at Montmagny (1925), and projected several others. Karl Moser in Switzerland was inspired to design his excellent St. Antonius in Basel (1926–27), and a whole school of new church architecture arose in Germany under Dominikus Böhm, Otto Bartning, and Rudolf Schwarz.

After this church renascence, however, a curious and unfortunate mediocrity characterized most French architecture, religious and secular (excluding, of course, the work of the Swiss-born Le Corbusier). After the Perrets' work at Le Raincy and Montmagny, few churches of real architectural merit were built in France until a second church-building movement was initiated after World War II. The revolution that the Perrets began in 1923 was rightly concerned with a fresh sweep in architecture; the new direction of the 1950s and '60s was primarily toward employing the finest contemporary artists in the church. As in past centuries of great church building, architect and artist worked hand in hand.

Father M. A. Couturier, O.P., was largely responsible for initiating this movement, and under his aegis a number of the greatest artists in France were invited to work on the church of Notre Dame de Toute Grâce at Assy, near Chamonix (Maurice Novarina, architect). This church was consecrated in 1950. Fernand Léger composed an enormous mosaic for the entrance, Jean Lurçat created a superb tapestry for the chancel, Georges Rouault and Henri Matisse designed the windows, while Jacques Lipchitz, Pierre Bonnard, Marc Chagall, Georges Braque, and Henri Laurens were among the other contributors. The architectural form, which is somewhat neo-Romanesque, is rather heavy and in no way equal to its art, and there is a lack of coordination in the art itself. This church, however, has had an extremely important influence throughout France and Europe. Architecture unaided by art can rarely reach the spiritual heights sought in a church because of its concern with the technical requirements of shelter.

After Assy a number of new churches were built with the active cooperation of architect and artist. One of these is Notre Dame des Pauvres at Audincourt (Doubs) (dedicated in 1951). Designed by Novarina, the building itself is simple and undistinguished, but gains distinction from the continuous band of 17 stained-glass windows by Léger and the entrance mosaic and baptistery glass by Jean Bazaine. The Léger windows are brilliant examples of contemporary thematic glass (they trace the Passion of Christ) while the abstract glass in the baptistery, with its warm, glowing colours, is a superb statement of nonobjective art.

A small semiprivate chapel of charm is that of Notre Dame du Rosaire, at Vence near Nice (1948–51), by Matisse. Again, the church is of secondary importance architecturally, but Matisse decorated it with superb tiles and glass and continued his lovely colours and motifs in the design of the vestments themselves; thus a complete integration of the visual arts, some fixed, some in motion, was achieved. The chapel at Vence is near the interesting old church at Villefranche-sur-Mer which Jean Cocteau redecorated.

It is generally held that the greatest masterpiece of contemporary French, indeed world, religious architecture is Notre Dame du Haut at Ronchamp, Haute-Saône (1955), by Le Corbusier. This startlingly original building is thought by many to be the most important church of the past several centuries, so profound is its impact and so creative its force. Although its architecture is almost completely nonderivative, recalling little of the past, the atmosphere within is intensely and very personally religious. It is an interesting contrast to the great Gothic cathedrals which, though incomparable monuments to God, tend to humble the worshiper.

The church exterior is dominated by the enormous upturned eave of the roof which projects far over the approach or south side and on the east side well over the outdoor pulpit and altar. The massive south wall, which is 12 ft. thick at the bottom and 5 at the top, commands the approach with a series of openings of various rectangular shapes dispersed irregularly across the front. Although these windows at first appear, both from without and from within, to have been placed haphazardly, their total effect is one of careful orchestration.

The interior of the church is likewise dominated by the roof, which according to the architect was inspired by the shape of the shell of a crab; it swoops down toward the middle like the underside of a great tent. The roof is not directly attached to the supporting walls, but rests lightly on blocks atop them so that the feeling of space, flowing over and out, is intensified. Although the physical dimensions of Ronchamp are modest, a mere 84 × 40 ft., with seats for only 50 persons, it gives an impression of a very great space. This effect is intensified by the subtle relation of three chapels subsidiary to the nave and by the deeply splayed windows, only a few of which are visible from any one spot. It is necessary to move about the church to appreciate its features; they cannot be grasped from a fixed position.

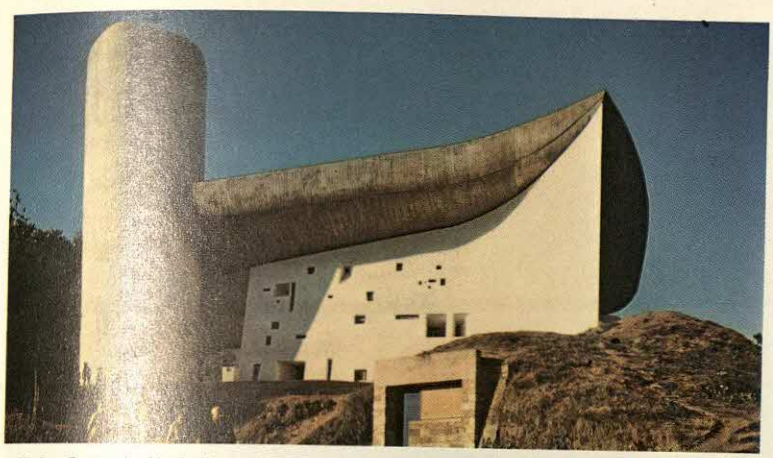
Other important postwar churches in France are: Sainte-Thérèse, Hem, Roubaix (1958), by Hermann Baur, with superb *Betonglas* by Alfred Manessier; Notre Dame, Royan (1958), by Guillaume Gillet; Saint-Rémy, Baccarat (1957), by Nicolas Kazis, with remarkable windows; the extremely virile and powerful "La Tourette" Dominican friary at Éveux (near Lyons) by Le Corbusier (1960); Saint-Joseph, Le Havre (1959), a startling "tower" church, by Auguste Perret (Raymond Audigier and Jacques Poirrier, associates); and the extraordinary underground basilica for 22,000 at Lourdes (1958), by Pierre Vago (Eugène Freyssinet, engineer).

Germany.—In tracing the background of contemporary German religious architecture the 19th century requires brief mention. Karl Friedrich Schinkel's St. Nicholas in Potsdam (1826–49) is the finest Neoclassic example, although obviously inspired by J. G. Soufflot's Panthéon in Paris. Sir George Gilbert Scott's St. Nicholas in Hamburg (1845–63), the nave of which was completely destroyed in World War II, was outstanding among the neo-Gothic. The Gothic revival also added a top to the ancient tower of Ulm Cathedral in 1877–90, making it the highest stone tower in the world (528 ft.).

Church architecture at the opening of the 20th century in Germany was stirring uneasily under the changing styles then prevalent. In the first years of the century several German architects, notably Theodor Fischer, made a tentative effort toward less derivative religious building, primarily by simplifying old clichés rather than attempting a genuinely fresh approach.

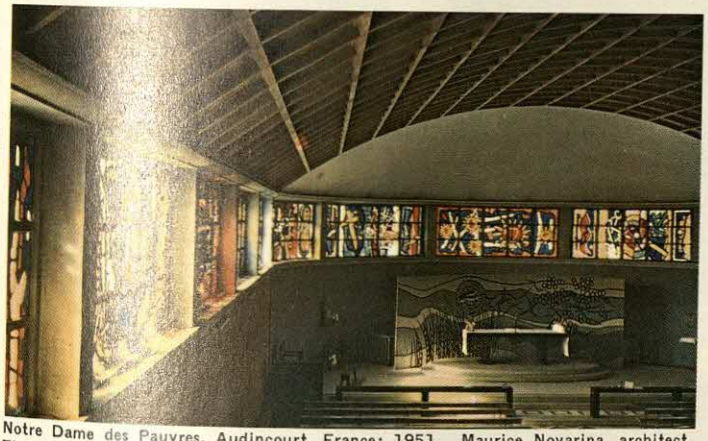
The first positive move was by Otto Bartning whose book *Vom neuen Kirchenbau* ("Toward a New Church Architecture") in

RELIGIOUS ARCHITECTURE



Notre Dame du Haut, Ronchamp, France; 1955. Le Corbusier, architect. (Above) The exterior walls are of concrete-reinforced stone, with a painted reinforced concrete double shell roof. (Right) Deep windows irregularly penetrate the walls of the interior

Cathedral Church of St. Michael, Coventry, Eng.; consecrated 1962. Sir Basil Spence, architect. The nave is seen through a glass wall engraved with translucent figures of angels and saints



Notre Dame des Pauvres, Audincourt, France; 1951. Maurice Novarina, architect. The windows by Fernand Léger trace the Passion of Christ

Notre Dame, Le Raincy, France; 1923. Auguste and Gustave Perret, architects. The slender concrete columns of the interior support the roof

Reformed Church, Zürich-Altstetten, Switz.; 1941. Werner Moser, architect

1919 was followed three years later by a model of his projected "Star Church." Although never built, it was a highly original and stimulating design which, together with the Perrets' church at Le Raincy, did much to awaken Germany to new church-building possibilities.

By 1926 several exciting new German churches had been constructed. These were Martin Weber's St. Boniface in Frankfurt am Main, and Dominikus Böhm's War Memorial Church in Neu-Ulm and his bold Catholic church at Bischofsheim. Böhm, in the latter church, took the reinforced concrete that the Perrets had confined to rigid boxlike frames and made it dramatically plastic. He built several other distinguished churches, among them St. Joseph at Hindenburg-Oberschlesien (1929) and St. Engelbert in Cologne-Riehl (1931).

Bartning, whose Protestant Steel Church for the Cologne Press Exhibition of 1928 was the great pioneer in steel, also designed two larger examples: the Round Church at Essen (1930), and the Gustav Adolf Church in Berlin-Charlottenburg (1934), later destroyed.

Rudolf Schwarz, who was to become Germany's most impressive church architect, designed a series of starkly simple but notable Catholic churches. The first was his Corpus Christi in Aachen, completed in 1930. Unquestionably one of the greatest religious architects of the 20th century, Schwarz in this, his first mature work (he was 33 at the time), showed promise of the Spartan directness and religious intensity that marked his subsequent designs.

After Hitler came to power in 1933 progressive thinking in architecture was muzzled. Schwarz, Böhm, and Bartning were largely inactive for 15 years, during which each thought deeply and maturely on the manifold problems of church building in the mid-20th century. Schwarz, probably the most profoundly religious of the three, published his *Vom Bau der Kirche* (1938) in which his architectural-religious concepts are set forth and illustrated by beautiful geometric diagrams.

When conditions finally permitted, all three set to work so actively and so successfully that Germany in a relatively few years became the leader in European religious architecture. Bartning designed a series of 48 emergency churches (*Notkirchen*), made from rubble and standardized salvaged material, while Böhm and Schwarz produced a number of new churches together with many reconstructions.

Postwar German churches are characterized by a daring, a willingness to experiment, and a directness which is very powerful. Among the most impressive examples are: St. Maria Königin, Cologne-Marienburg (1954), by Dominikus Böhm, with a lovely wall of stained glass; St. Mauritius, Saarbrücken (1956), by Albert Dietz; the very powerful Kaiser-Wilhelm-Gedächtniskirche, Berlin (1961), by Egon Eiermann; Christ Church, Bochum (1959), by Dieter Oesterlen; St. Joseph, Hasloch-am-Main (1958), by Hans Schädel; Maria Regina Martyrum, Berlin (1962), by Schädel and Friedrich Ebert; Paul Gerhardt Church, Mannheim (1960), by Gerhard Schlegel and Reinhold Kargel; and the following by Rudolf Schwarz: Holy Cross, Bottrop (1957), St. Anna, Düren (1956, one of the great churches of modern times), St. Michael, Frankfurt am Main (1954), Church of the Holy Family, Oberhausen (1958), and Maria Königin, Saarbrücken (1959).

Switzerland.—The contemporary church movement in Switzerland is, after the German and French, the most productive in Europe. Starting with Karl Moser's superb St. Antonius in Basel (1927) and continuing through the 1930s and '40s when Germany and France built little of merit, the Swiss built an impressive number of fine new churches. Having, like Germany, slightly more Protestants than Catholics, Switzerland profited from the stimulating reaction the religious architecture of each group had upon that of the other.

Following the Catholic initiative in Moser's St. Antonius, the Protestants, after a competition in 1931, launched their contemporary church building with St. Johannes in Basel (1936), by E. F. Burckhardt and Karl Egender. There followed a number of sensitively designed, handsomely detailed and constructed churches, both Protestant and Catholic.

The outstanding church in the country is the Reformed Church at Zürich-Altstetten (1941), by Werner Moser, the son of Karl Moser. Other churches of particular interest are: All Saints, Basel (1953), and Bruderklausen, Basel-Birsfelden (1959), by Hermann Baur; Reformed Church, Effretikon (1961), and Reformed Church, Oberglatt (1964), by Ernst Gisel; Liebenfels Cemetery Chapel, Baden (1957), by Edi and Ruth Lanners and Res Wahlen; and St. Francis, Basel-Riehen (1950), by Fritz Metzger.

Great Britain.—During the 19th and early 20th centuries architecture in England followed the cultural pattern of France. Neoclassicism was strong until the mid-19th century, but primarily influenced banks, clubs, and public buildings, not church architecture. The Gothic revival enjoyed a more active popularity in England than in any other European country: because of its almost continuous use in religious work, notably interrupted by Sir Christopher Wren who considered Gothic barbaric, the English Gothic revival has been referred to as the "Gothic survival." Neoclassicists and Gothicists in England fought so heatedly that their controversy was dubbed the "battle of the styles." A compromise of sorts was effected whereby most public buildings were designed in a watered-down Classical or Renaissance tradition, while most churches were Gothic.

Few churches built in England in the 19th and early 20th centuries were not inspired by the Gothic. The two most imposing examples are John Bentley's large Roman Catholic cathedral in Westminster, London (1895–1903), a curious pseudo-Byzantine edifice, and Sir Giles Gilbert Scott's enormous Liverpool cathedral, begun in 1903.

The contemporary church-building movement of the 1920s which took such an exciting hold of the continent had little effect in the British Isles. After World War II English church architecture received a decided stimulus from Basil Spence's winning design for the rebuilding of Coventry cathedral (1962). Several other progressive churches should be mentioned but they are distressingly few in number: St. Paul's, Bow Common, London (1960), by Robert Maguire, and St. Matthew, Perry Beeches, Birmingham (1963), by Maguire and Keith Murray; and Edward Mills' Methodist Church, Mitcham, Surrey (1959).

Scandinavia.—The development of architecture in Scandinavia before the 20th century followed at a discreet distance the fashions of the continent. Few buildings of international distinction were to be found. After Gunnar Asplund's Stockholm Exposition of 1930, however, Sweden, Finland, Denmark, and Norway contributed greatly to the richness and vocabulary of contemporary architectural thought. In some respects, such as land usage and housing, Scandinavia, and Sweden in particular, led the world.

The religious architecture after 1930 was also significant. Erik Bryggman's cemetery chapel in Turku, Fin. (1941), is one of the influential contemporary churches in Scandinavia, distinguished by its sensitive proportions and a wall of glass opening onto its park-like setting. Other notable Finnish churches are: the famous Vuoksenniska Church, Imatra (1958), by Alvar Aalto; Village Church, Hyvinkää (1961), by Aarne Ruusuvuori; a delightful chapel for the Technical University at Otaniemi, Helsinki (1957), by Kaija and Heikki Siren, and an unusual church by the same architects at Orivesi (1962).

In Sweden, few distinguished contemporary churches were built until the late 1950s—Ivar Tengbom's Högalid Church in Stockholm (1923) being an early exception. Sweden in the 1940s did, however, produce two of the world's most beautiful crematoria: Gunnar Asplund's Woods Crematorium in Stockholm (1940), one of the great monuments of modern architecture, and Sigurd Lewerentz' crematorium in Malmö. Some interesting churches are: St. Thomas, Vällingby, Stockholm (1960), by Peter Celsing; a superb cemetery chapel at Gävle (1959), by Engström, Landberg, Larsson, and Törneman; the highly imaginative Skarpnäck Church, Stockholm-Björkhagen (1961), by Lewerentz; the Farsta Church, Stockholm-Hökarängen (1960), by Bengt Lindroos and Hans Borgström; and the impressive Västerort Church, Vällingby, Stockholm (1956), by Carl Nyrén.

Architecture in Norway has always lagged behind that in the rest of Scandinavia. The most brilliant facet of Norway's contribution

to architecture lies in its churches of the Middle Ages. From the 11th through the 13th centuries there were built, largely in the country's more remote regions, 500 to 600 stave churches. Intensely personal and highly carved and painted, these almost pagan wooden churches are unique in ecclesiastical architectural history. Only 22 were extant in modern times. The village church at Gravberget (1956), by Magnus Poulsson, is the finest recent example.

Of the 20th-century churches in Denmark, P. V. J. Klint's Grundtvig Church in Copenhagen (1913–40) is the most nationalistic in flavour (it recalls the traditionally Danish stepped gables), its facade suggesting a gigantic series of organ pipes in brick. Several more convincing recent examples—all near Copenhagen—are: St. Knud Lavard, Kongens Lyngby (1957), by Carl R. Frederiksen; Crematorium Chapel, Glostrup (1960), by Bornebusch, Brüel and Selchau; and Stengård Church, Gladsaxe (1963), by Graae and Wohlert.

Italy.—The Italians, having the most magnificent inheritance of fine churches in the world, were little disposed to construct more until the unparalleled devastation of World War II. Although several churches were built in contemporary style in Italy in the 1930s, none compared with the advanced work done by that time in Germany, Switzerland, and France. Even by the mid-1960s there were fewer fine new churches in Italy than in the northern countries, but both quantity and quality have improved steadily and the climate for progressive religious architecture is excellent. Among the impressive postwar churches are: Madonna of the Poor, Milan (1952), by Luigi Figini and Gino Pollini—brutalist but full of character; the imaginative, translucent-walled Matri Misericordiae at Milan-Baranzate (1958), by Angelo Mangiarotti and Bruno Morassutti; Sta. Maria Maggiore, Francavilla al Mare (1959), by Ludovico Quaroni; and the fantastic Church of the Autostrada, near Florence (1963), by Giovanni Michelucci.

Elsewhere in Europe.—Of the remaining countries of Europe few contributed significantly to religious architecture in the 20th century, although some good work was done in most of them. After World War I Czechoslovakia produced several advanced churches, notably St. Wenceslaus in Prague (1930), by Josef Gočár, but after 1939 little work of merit was done.

The Dutch after World War II constructed a series of good churches. Among the most successful are: Reformed Church, Aerdenhout (1958), by Karel L. Sijmons; Reformed Church, Nagele (1960), by van den Broek and Bakema; Reformed Church, Geleen (1956), by Bart van Kasteel; and St. Nicolas, Venlo (1961), by G. J. van der Grintin.

The most fantastic church of the 20th century is the Church of the Holy Family in Barcelona, Spain, by Antonio Gaudí which embodies many leading characteristics of Spanish *art nouveau*. Although begun late in the 19th century the church was never completed. Its lofty towers and facade are original and imposing; they recall a child's seaside castle of wet sand drippings. Two later and very stimulating churches—both in the small city of Vitoria—are the Church of Our Lady of the Angels (1959), by Javier Carvajal Ferrer and José García de Paredes; and the Church of the Coronation of Our Lady (1960), by Miguel Fisac.

Ibero-America.—In spite of the great growth of all Latin-American countries in the 20th century only a few significant churches have been built. The best of these are in Brazil and Mexico, the two countries that also have the richest architectural heritage from their colonial eras. One of the most provocative is Oscar Niemeyer's San Francisco in Belo Horizonte, Braz. (1943). Niemeyer's design for the cathedral for Brasília (1962), the new capital of Brazil, is startlingly handsome.

The development of contemporary architecture in Mexico was vigorous, and several churches there had influence beyond Mexico itself. One of these is Enrique de la Mora's Church of La Purísima in Monterrey (1947), constructed of intersecting paraboloids of concrete. Although details and lighting are clumsy, the structure is good. Much more successful is Felix Candela's Church of the Virgin of the Miraculous Medal in Mexico City (1954). Candela, one of the world's great experts in thin-shell warped concrete surfaces, or hyperbolic paraboloids, helped pioneer highly promising developments in reinforced concrete. Candela tended to free reinforced concrete from rigid boxlike shapes, rectangular beams, and flat slabs like wood and steel, and used it instead in thin, very strong curved planes, like eggshells and folded pieces of paper. The Church of the Virgin is so refined structurally that the roof is only 1½ in. thick. The aesthetic potential of concrete is enormous and Candela made bold use of it in this church, particularly on the interior. Unfortunately the finished churches are not so elegant as their structure. Others by Candela using this material are La Capilla de Nuestra Señora de la Soledad, Mexico City (1957); and San Vicente de Paul, Mexico City (1960).

United States.—The United States has an architectural heritage of some of the loveliest and most appealing small churches ever built. Outstanding among these are the 17th- and 18th-century village churches and meetinghouses, primarily Congregational and Unitarian, scattered throughout much of New England and eastern New York State. These simple white wood structures, with their tall spires, have an inherent rightness, a sense of belonging architecturally, which makes them one of the country's finest cultural contributions.

The colonists in the South brought to Virginia an established liturgy and church-building program. The program was of necessity modified somewhat by local conditions, but the 17th- and 18th-century churches of Southern colonial and Georgian inspiration reflected the Old World far more than did the churches and meetinghouses of New England. Equally reminiscent of Europe were the buildings that the Spaniards built from Florida to California. Their churches, missions, and public buildings stem in large part from Iberian models.

As the American colonies coalesced under English dominance, religious building increasingly reflected the fashions and developments of the British Isles. Sir Christopher Wren and James Gibbs inspired churches from Boston (Christ Church, 1723) to New York City (St. Paul's Chapel, 1764–66) to Charleston (St. Michael's, 1752–61). Following the Revolution a self-consciously nationalistic federal architecture arose, strongly abetted by Jefferson's enthusiasm. It evolved directly from the Classical revival then sweeping Europe, particularly France, the new nation's important friend. The general Classical revival was followed by the specific Greek revival; at mid-19th century came the Gothic revival and after that a potpourri.

Richard Upjohn's Trinity Church (1839–46), James Renwick's Grace Church (1845–6), and St. Patrick's Cathedral (1858–79), all in New York City, are among the country's outstanding Gothic revival churches. External form, however, not structural purity, was predominant. St. Patrick's vaults are not self-supporting; its flying buttresses receive no load.

U.S. architecture in most of the first half of the 20th century lagged far behind that of Europe, except in skyscraper construction. Notable buildings were built, but they were few in number and not widely accepted. After World War II, however, the U.S. produced a great many excellent structures in all categories and public acceptance of new work was widespread.

The contemporary tradition in U.S. church building has distinguished roots in Unity Temple, Oak Park, Ill., built in 1906 by Frank Lloyd Wright, and in the First Church of Christ Scientist, Berkeley, Calif. (1910), by Bernard Maybeck. Although neither constituted the architectural revolution which the Perrets' church at Le Raincy occasioned, they are unquestionably landmarks in the evolution of contemporary church architecture. Wright's other religious buildings include his chapel at Florida Southern College, Lakeland (1941), the First Unitarian Church in Madison, Wis. (1951), the striking Beth Sholom Synagogue in Elkins Park, Pa. (1958), and a circular Greek Orthodox church of dubious detail in Milwaukee (1961). His son, Lloyd Wright, built one of the country's memorable churches, the beautifully situated Wayfarer's Chapel at Palos Verdes, Calif. (1951). The design is composed basically of frames of redwood and sheets of clear glass so that the sea and surroundings become an intimate part of the service itself.

Pietro Belluschi, who went from Italy to the U.S. in 1923, designed a number of churches which are models of elegant simplicity, sympathetic scale, and carefully considered natural lighting. His Zion Lutheran, Portland, Ore. (1951), First Presbyterian,

Cottage Grove, Ore. (1951), Church of the Redeemer, Baltimore (1958), with Rogers, Taliaferro, and Lamb, and his Portsmouth Priory, Portsmouth, R.I. (1959), with Anderson, Beckwith, and Haible, greatly encouraged and enriched the U.S. church-building scene.

Eliel Saarinen and his son, Eero, both born in Finland, were among the pioneers in contemporary U.S. church design. Their Tabernacle Church of Christ in Columbus, Ind. (1942), was one of the important earlier ones built in the U.S. They collaborated even more successfully in Christ Lutheran Church in Minneapolis, Minn. (1950), which was Eliel Saarinen's last work. The younger Saarinen then designed the nonsectarian cylindrical Kresge Chapel at Massachusetts Institute of Technology in Cambridge (1956), a brilliant example of religious architecture, and several college chapels, notably at Concordia College, Fort Wayne, Ind. (1958). His last design before his death (1961) at 51 was the North Christian Church, Columbus, Ind. (1964). Louis I. Kahn's First Unitarian Church at Rochester, N.Y. (1963), quickens interest in that its nave is lit only by skylights, its walls being solid. Another university chapel of note is at the Illinois Institute of Technology, Chicago (1952), by Ludwig Mies van der Rohe.

Two striking religious buildings of large size are the Air Force Academy chapel at Colorado Springs, Colo. (1961), and the First Presbyterian Church in Stamford, Conn. (1958). The Air Force Academy chapel is of aluminum-skinned tetrahedral frames, graphically suggesting the spirit of the air age. Skidmore, Owings, and Merrill were the architects, and Gordon Bunshaft and Walter Netsch the designers. Wallace Harrison's Stamford church is powerful although overly attenuated in plan and fussy in detail. Its exterior is of canted, angular planes, resembling some great fish, with a soaring colour-drenched nave within. A dazzling flood of light fills the interior from windows that rise from the floor to the ceiling ridge. These windows are filled with 20,000 pieces of inch-thick *Betonglas,* designed by Harrison and executed by Gabriel Loire of Chartres, France.

Harrison and his partner, Max Abramovitz, also designed an interfaith centre for Brandeis University, Waltham, Mass. (1955). Instead of a single convertible building for the three faiths represented, there are three separate, individual chapels, Jewish, Protestant, and Catholic, sensitively grouped around a common pool and landscaped setting.

Synagogue architecture in the U.S. is at times of a high level. Eric Mendelsohn, who lived in the U.S. from 1941 to his death in 1953, designed several fine temples, as has Percival Goodman. Two of the handsomest synagogues in the U.S.—in addition to Wright's at Elkins Park—are the Temple Emanu-el, Dallas, Tex. (1957), by Howard R. Meyer and Max Sandfield (with W. W. Wurster, consultant), and Philip C. Johnson's elegant Kneses Tifereth Israel Synagogue in Port Chester, N.Y. (1956). This clean, geometrically precise temple is a sharp contrast to the freer, more rugged design of Wallace Harrison's First Presbyterian Church in Stamford, less than ten miles away. Though poles apart architecturally, they are among the finer religious buildings in the country.

In contrast to its magnificent accomplishments in Europe, the Catholic Church in the U.S., as in Latin America, espoused relatively traditional church forms for new building. In the first half of the 20th century there were few Catholic churches of distinctive contemporary design. Among the most notable Catholic buildings are Robert Anshen and W. S. Allen's Chapel of the Holy Cross, Sedona, Ariz. (1956), Belluschi's Portsmouth Prior Chapel already mentioned, Marcel Breuer's very impressive Benedictine Abbey of St. John in Collegeville, Minn. (1961), and his Annunciation Priory in Bismarck, N.D. (1962), and Hellmuth, Obata, and Kassabaum's St. Louis Priory Chapel (1962).

Two Protestant churches are of interest in that they illustrate the problems of the automobile age: St. Clement's Episcopal Church, Alexandria, Va. (1948), by J. H. Saunders and the former rector, Darby Betts; and the Venice-Nokomis Presbyterian Church, Venice, Fla. (1953), by Victor A. Lundy. The first, being flanked by roads with noisy traffic, is of windowless, soundproofed design, artificially lit and air conditioned. The Florida chapel is just the reverse: it is an open-air, drive-in church. Lundy has also done a fine First Unitarian Church in Westport, Conn. (1961), and the First Unitarian Congregational Church at Hartford, Conn. (1964).

REMAGEN, a town of West Germany in the *Land* (state) of Rhineland-Palatinate (Rheinland-Pfalz), Federal Republic of Germany, lies on the left bank of the Rhine, 19 km. (12 mi.) SSE of Bonn. Pop. (1961) 7,244. It was the old Roman fortress Rigomagus and has some Roman remains. It developed as a small medieval town and has a gate dating from the 12th century; there is now a continuous series of hotels along the Rhine waterfront. In the Allied advance to the Rhine in World War II, the 9th Armored Division of the United States 1st Army discovered on March 7, 1945, that the railway bridge at Remagen, though damaged, was usable. It promptly forced a crossing and established the first Allied bridgehead across the Rhine, which on March 25 became one of the spearheads of the Allied attack into the heart of Germany. (R. E. Dr.)

REMAINDER THEOREM, a theorem of particular value in the study of polynomials and equations. If we divide

$$2x^2 + 3x + 6 \text{ by } x - 2$$

for example, the quotient is $2x + 7$ and the remainder is 20. The remainder, however, can be found by substituting 2 for x in the polynomial. This gives:

$$2 \cdot 2^2 + 3 \cdot 2 + 6 = 8 + 6 + 6 = 20$$

More generally, to find the remainder arising from dividing $f(x)$ by $x - r$, substitute r for x in $f(x)$. This evidently amounts simply to evaluating $f(x)$ for some special value (r) of x. This is conveniently done by following the plan shown at the right. This work reveals not only the remainder (20) but also the coefficients ($2 + 7$) of the quotient ($2x + 7$). When used for this latter purpose it is known as synthetic division. This method of dividing is very helpful in finding the roots of numerical higher equations.

REMARQUE, ERICH MARIA (1898–), German novelist, was born on June 22, 1898, in Osnabrück. He achieved world fame as author of *Im Westen nichts Neues* (1929; Eng. trans. by A. W. Wheen, *All Quiet on the Western Front,* 1929), a vehement antiwar novel which, because of its sensational realism, caused a considerable controversy in Germany. Its sequel *Der Weg zurück* (1931; Eng. trans. by A. W. Wheen, *The Road Back,* 1931) describes the collapse of Germany in 1918 and the subsequent political disorders. Remarque fought in World War I and was later a teacher and journalist. He left Germany in 1932 for Switzerland, but in 1939 went to New York where he became a

U.S. citizen. After World War II he returned to Switzerland. Of his many other novels only *Arc de Triomphe* (1946; Eng. trans. by W. Sorell and Denver Lindley, 1946) was a world success.

(H. S. R.)

REMBRANDT (Rembrandt Harmensz [or Harmenszoon] van Rijn [or Ryn]) (1606–1669), the outstanding genius of the Dutch school of painting in the 17th century, was born in Leiden on July 15, 1606. His father, Harmen Gerritsz van Rijn, was a miller, while his mother, Neeltgen (Cornelia), was the daughter of a baker, Willemsz van Zuytbrouck, and they appear to have been simple, industrious and deeply pious folk, typical of the Dutch lower-middle class of this period. They originally intended him for a scholastic career and at about the age of seven he entered the Latin school in Leiden. In 1620, when not quite 14, he was enrolled in the university but he did not stay there long. In the following year his parents recognized that his talents as well as his inclinations lay in the direction of painting and he was apprenticed for three years to Jacob Isaacsz van Swanenburgh, a minor painter of architectural subjects. Rembrandt can have learned little from Swanenburgh beyond the basic elements of technique, for there is not the least trace of his first master's style in any of his work.

In 1624, having completed his apprenticeship, he went to Amsterdam for six months as a pupil of the historical painter Pieter Lastman, a far more talented artist than Swanenburgh. Lastman was a capable painter, but his somewhat theatrical style lacked any kind of profundity and he cannot have played an important part in developing that depth of human sympathy which is perhaps Rembrandt's most personal and valuable quality. However, at the more superficial level of subject matter and imagery—the visual vocabulary of Rembrandt's art—the influence of Lastman was powerful and enduring. Lastman was one of a small group of Dutch artists who had worked in Italy during the first decade of the century and were associated with the German master Adam Elsheimer (*q.v.*). The work of this group was strongly influenced by the 16th-century masters of Venice, notably Tintoretto, and in this they are quite distinct from the Dutch followers of Caravaggio, such as Gerard van Honthorst, Hendrick Terbrugghen and the other Utrecht painters, who were the principal channel of Italian influences in Holland at the time when Rembrandt was reaching maturity. Tintoretto and Caravaggio were both masters of chiaroscuro, using violent contrasts of light and shade for dramatic effect, but their methods were almost diametrically opposed, and the fact that Rembrandt's early contacts were not with the Utrecht school but with Elsheimer's followers in Amsterdam may well have been an important factor in the formation of his own chiaroscuro style. The contrast of searching light and deep shadow is one of the central elements of Rembrandt's art, and his employment of it approaches more closely to the spirit of Tintoretto—emotional, mysterious, nonnaturalistic and even arbitrary in treatment of the play of light and its source—than to the almost brutal naturalism and the quasi-scientific handling of light that characterize Caravaggio and his followers. The link with Tintoretto via Elsheimer can be traced more clearly through the works of the Pynas brothers (*e.g.*, Jan Pynas' "Raising of Lazarus," in Philadelphia) than through Lastman himself, for whom the major Venetian influence was that of Veronese. In Lastman's biblical and historical compositions the delicate daylight of Veronese takes on a cruder glare, and the cultured urbanity of Veronese's poses and gestures becomes pompous and provincial, but none the less the youthful Rembrandt found Lastman worth imitating and there are many echoes of his master in the historical pictures which he painted in Leiden between 1625–31. Examples of these are: "The Prophet Balaam" (1626; Cognacq-Jay museum, Paris) and "David Presenting the Head of Goliath to Saul" (1627?; Smidt van Gelder collection, Amsterdam), of which the latter is virtually a Lastman in miniature. Other works of these years, such as "The Tribute Money" (1629; Beit collection, London) show his growing interest in the use of expressive chiaroscuro. Rembrandt was naturally very much alive to influences other than the Italianism of the Lastman school. In addition to occasional hints borrowed from such contemporaries as Frans Hals and Adriaen Brouwer (*qq.v.*) one can detect the persistence of the northern genre tradition of the previous century, with its love of elaborate still-life details, in such a picture as "Tobit, His Wife and the Kid" (1626; in the private collection of Baroness Bentinck von Thyssen).

So far Rembrandt has been considered only as a painter of classical and biblical themes, but already in this early period a large proportion of his work consisted of portraits and studies of single figures and he was also making his first experiments in etching, a medium in which he was later to achieve unsurpassed results. The sitters for the portrait studies were frequently members of his own family, the most frequent being himself. These are not portraits in the fashionable sense, but studies in character, expression and lighting that could be (and often were) used in his subject pictures. The borderline between portraiture, genre and historical art is often a shadowy one, as when he paints "The Artist's Mother as the Prophetess Hannah" (1631; Rijksmuseum, Amsterdam), or develops a study of an old man into "The Apostle Paul" (Museum, Nürnberg). Often his homely sitters are given an exotic look by being made to wear some piece of extravagant headgear—a colourful turban, a helmet or a curiously plumed hat —as an exercise in the rendering of textures and effects of light. Most of the pictures of this period are painted on panel, with a predominance of cool, grayish monotone in the colouring, and the technique, though vigorous, is tighter and more constrained than the broad, loose brushwork of his later years. He soon became known in Leiden, where he shared a studio with the almost equally promising Jan Lievens, and before his removal to Amsterdam he was already taking pupils, among whom the most notable was Gerard Dou. More important for his subsequent career, he had roused the interest and admiration of Constantijn Huygens, with whose remarkable family he appears to have remained in contact throughout his life.

In the latter part of 1631 Rembrandt moved from Leiden to Amsterdam, the city which by this time had risen to be the foremost mercantile and artistic centre in Holland. Since he had already received a number of commissions from patrons in Amsterdam, he no doubt felt reasonably assured of a successful future there, and in fact the next ten years were to be—in terms of material reward—the most successful period of his life. He quickly gained a lion's share of the market in middle-class portraiture, in competition with such established and competent masters as Thomas de Keyser, and was commissioned (*c.* 1633) to paint a series of scenes of the Passion for the stadholder, Frederick Henry, prince of Orange, probably through the good offices of Constantijn Huygens, who was the stadholder's secretary. In 1634 he married Saskia van Uylenburch, a relative of his landlord and business associate, the art dealer Hendrick van Uylenburch. Saskia brought a considerable property of her own as marriage portion, for her family was both wealthy and well connected, and the rise in Rembrandt's fortune and social status is fully reflected in the confident and extrovert mood of much of his work of the 1630s. In his art as in his life this was a period of growth and expansion, and the centre of both life and art was the personality of his attractive young wife. In the "Self-Portrait With the Artist's Wife" (Dresden museum) Rembrandt, jovial and resplendent in "cavalier" costume, is seated at a richly garnished table, one hand raising a drinking glass while the other clasps the waist of Saskia, who sits perched, rather demurely, on his knees. It would be foolish to regard this as a literal glimpse into their home life, but it is, in its somewhat vulgar exuberance, Rembrandt's most joyful testimony of his own pleasure in the good things of life.

Doubtless he did enjoy life, but he worked hard also, enlarging his achievement as well as his ambition in a splendid succession of portraits, historical pieces, etchings and drawings. He painted on a larger scale than in his Leiden years, with an increasing preference for canvas rather than panel. His colouring grew warmer, with brown and golden tones predominating, and his brushwork began to develop toward the unrivaled breadth and expressiveness of his fullest maturity. His first big portrait commission was in 1632 for the Surgeons' guild in Amsterdam—"The Anatomy Lesson of Professor Nicolaes Tulp" (Mauritshuis, The Hague). The official group portrait, depicting the officers of a guild, civic guard

BY COURTESY OF RIJKSMUSEUM

LEFT, "NIGHT WATCH" BY REMBRANDT; RIGHT, DETAIL OF CENTRAL FIGURE. IN THE RIJKSMUSEUM, AMSTERDAM

or other corporate body, was an established and important genre in Holland (as nowhere else) and "anatomies" had already been painted by De Keyser and others, although before Rembrandt's time such pictures had tended to be somewhat rigid assemblages of individual portraits, without psychological or pictorial unity in any marked degree. Hals in his earlier groups of the Haarlem civic guards moved toward a more pictorial solution, but Rembrandt penetrates far more deeply into the human situation. Without false overemphasis his "Tulp" reveals the inherent drama of the moment, contriving at the same time to convey the humane and compassionate motives which underlie an otherwise macabre operation, and it was an important step forward in the direction of his own "Night Watch" and "Syndics." In many of his portraits of this period Rembrandt aimed at the neat and highly finished effects which characterized the work of most of his rivals, as can be seen in such pictures as the pair of oval bust-length figures (Boston Museum of Fine Arts) of an "Unknown Man" (1634) and a "Lady in a Lace Collar," or the splendid pair of full-lengths (in the private collection of Baron Robert de Rothschild) also painted in 1634, which were thought to be portraits of Maerten Daey and his first wife Machteld van Doorn, but which more probably represent Marten Soolmans and his wife Oopjen Coppit, who after the death of her husband married Maerten Daey as his second wife. Among many other fine portraits of this phase are: the undated companion pieces of "Jan Pellicorne With His Son" and of Pellicorne's wife "Susanna van Collen With Her Daughter" (Wallace collection, London); "The Shipbuilder and His Wife" (1633; Royal collection at Buckingham palace, London); "The Preacher Eleazar Swalmius" (1637; Antwerp museum); "The Mennonite Preacher Cornelis Anslo and His Wife" (1641; Berlin); "Saskia as Flora" (1634; Hermitage, Leningrad); and the "Self-Portrait" of 1640 (National gallery, London), which shows the artist at the height of his fame and prosperity. In addition Rembrandt continued to produce many studies of a more personal kind, such as heads and single figures of old men, or Jewish types in turbans or colourful robes, that could be of use in his historical paintings.

The biblical subject pictures of these early years in Amsterdam are richly varied and provide evidence that Rembrandt studied almost every contemporary current in European painting. "Christ Appearing to Mary Magdalene" (1638; Buckingham palace) and the "Visitation" (1640; Detroit Institute of Arts) continue and enrich the Elsheimer tradition. The "Sacrifice of Abraham" (1635; Hermitage) is a fully baroque design of spiraling movement. Three illustrations of the story of Samson contrast with the pictures mentioned above and with each other: "Samson Threatening his Father-in-Law" (1635; Berlin) is a straightforward scene of comedy in which the painter's own features can be recognized in the guise of the irate hero; "The Blinding of Samson" (1636; Städelsches Kunstinstitut, Frankfurt-on-Main) is a piece of savage melodrama and perhaps the most Caravaggesque of all Rembrandt's pictures; while "Samson's Wedding Feast" (1638; Dresden museum) is a sumptuous banqueting scene, in which the composed and charming figure of Saskia (Delilah) forms the central key of the composition. "The Sacrifice of Manoah" (1641; Dresden) gives a foretaste of the simplicity and the depth of feeling of Rembrandt's later religious paintings. In spite of the stylistic diversity of these works, they are all deeply impressed with the stamp of Rembrandt's individuality and humanity. Jakob Rosenberg observed that Rembrandt was never inclined to separate the human point of view from the pictorial. In this lies the peculiarly moving quality of his art, that no imitator could approach. His paintings testify to an intimate and loving knowledge of the Bible stories and he presents their characters always as samples of common humanity, not as remote and superhuman protagonists of legend or fairy tale. For Rembrandt the Bible was simple fact—and to be treated as such. The five pictures of the Passion cycle (1633–39; Ältere Pinakothek, Munich) contain all these elements of style and character. In them can be traced echoes of Tintoretto, Caravaggio, Lastman and of Rubens' great "Descent From the Cross" in Antwerp cathedral, but all are fused in the concentrated and forthright power of Rembrandt's own manner, which owes nothing crucial to any of them. All are imbued with the painter's profound compassion, and in the first of the series ("The Raising of the Cross") he painted his own troubled face among the soldiery who heave the cross into position—and who shall be forgiven because "they know not what they do."

From about 1636 onward Rembrandt produced a small number of landscapes, most of them on panel and small, or fairly small, in size. Representative examples are: "Landscape With a Stone Bridge" (1637–38; Rijksmuseum); "Landscape With an Obelisk"

(1638; Isabella Stewart Gardner museum, Boston); the comparatively large "River Landscape With Ruins on a Hill" and the tiny "Winter Landscape" (1646; both in the museum, Cassel, Ger.). These pictures strike one almost as being occasional relaxations of the artist from the hard discipline of figure painting, for they are free and spontaneous in design and technique. In general they follow the tradition of such landscape masters as Pieter Molijn, the early Jan van Goyen and Hercules Seghers, painted almost in monochrome but enlivened by spirited brushwork and dramatic tonal contrasts. Rembrandt delighted in painting an overcast or stormy sky, pierced by a single brilliant shaft of sunlight which illumines a building, a bridge or a clump of trees, producing a "spotlight" effect parallel to that of his figure and interior subjects. There is not the space here for a detailed consideration of Rembrandt's etchings, but among the more important plates of this phase are "The Raising of Lazarus" (*c.* 1632), "Christ Before Pilate" (1636) and "The Death of the Virgin" (1639).

The celebrated picture known as "The Night Watch" (Rijksmuseum), which was completed in 1642, may be regarded with some truth both as the culminating masterpiece of this decade of successes and as representing the transition to Rembrandt's later and less prosperous years. It might more accurately (though less succinctly) be called "The Civic Guard Under Captain Frans Banning Cocq and Lieutenant Willem van Ruytenburch," for the thorough cleaning which it received in 1946–47 proved that it was not a night scene at all, but that the crowd of figures are emerging into sunlight from the shadows of an arched gateway. It is a huge canvas, about 12 ft. high by 14½ ft. wide, and was originally even larger. Early copies show that the painting has since been cut down on all sides and especially drastically at its left edge, where two figures have been entirely lost. The composition has suffered from this curtailment, but it remains one of the supreme achievements of European art, baroque in its surging yet unified movement and its dramatic yet unified chiaroscuro, but a baroque which Rembrandt keeps under firm control by the strength of his design. "The Night Watch" also provides a foretaste of the brighter colouring that was to appear in his late style though, characteristically, it is used sparingly and effectively against a dark background. The captain's bright red sash and the lieutenant's yellow uniform provide the principal chord of colour, which is echoed in more muted tones in the reds and orange-browns of the figures on each side of them and in the paler yellow of the little girl's dress, while in the background and at the sides cooler greenish and yellowish tints predominate. To achieve the splendid unity of this complex composition Rembrandt subordinated the claims of portraiture to those of his own imaginative genius. This may well have dissatisfied some of the sitters who are placed in such deep shadow as to be almost invisible, but it is surely too much to assume, as many have done, that the decline in his popularity from about this time is directly attributable to the cool reception of this masterpiece. As a body the shooting company of Captain Banning Cocq can hardly have been displeased at acquiring a work of such evident splendour.

From 1640 onward a series of misfortunes overtook Rembrandt. In 1640 his mother died and in 1642 he suffered a still more grievous loss in the death of Saskia, a few months after the birth of their one surviving child, a son. This boy, christened Titus, was thenceforth the apple of his eye and he painted many portraits of him in childhood and as a young man. His popularity as a painter was on the wane, for patrons were turning their attention to the glossier and more readily comprehensible style of the younger generation, a style to which Rembrandt made no concessions. On the contrary, he followed undeviatingly the path of his genius toward ever broader and less "finished" effects. In 1639 he had bought a large and imposing house in the Jodenbreestraat, which contributed to his troubles for he could not really afford its upkeep, and for several years he sank deeper and deeper into financial difficulties. In 1656 he was declared bankrupt, and by 1660 the fine house and almost all of his possessions, including valuable pictures and a vast assortment of armour and other curiosities, had been sold to pay what could be paid of his debts and he had moved into a humble lodging in a poorer quarter of the city. With him went Titus, now a youth of about 18, and Hendrickje Stoffels, who had entered his household as a servant girl in about 1645 and remained with him in his years of adversity as his mistress and loyal helper. Hendrickje and Titus formed a business partnership as dealers in works of art, with Rembrandt nominally their employee, bound to hand over to them all that he produced in return for his food and lodging. This ingenious device afforded him some protection from his creditors and permitted him at least to work unmolested as old age drew nearer. But his misfortunes were not ended. Hendrickje died in 1662, and in 1668 Titus died, only a few months after his marriage to Magdalena van Loo. Rembrandt did not long outlive his son. He died on Oct. 4, 1669, and was buried in the Westerkerk on Oct. 8. He was survived by his daughter Cornelia, born to Hendrickje Stoffels in 1654. The hardships of Rembrandt's old age have been much exaggerated by some writers, who have pictured him as almost entirely neglected after his brief period of prosperity. This was not really the case. Although no longer a successful painter in the material sense, he was far from being forgotten, as contemporary accounts fully prove. As late as 1662 he executed an important commission, the superb groups of "The Syndics." The failure of contemporary taste to accept the ultimate achievements of his late style was a fate that other great artists have endured in old age. For Rembrandt, as for them, the fulfillment of his art was more important than the applause that he might gain; his triumph was that he spurned any ignoble compromise.

It is no easy task to single out individual pictures for mention from the wealth of masterpieces which Rembrandt produced in the final phases of his career. The self-portraits, which stretch in an unbroken series from his youth to the end of his life to form an artistic autobiography of the most fascinating and moving kind, take on a more sombre and troubled look. In such examples as the half-length "Self-Portrait" of 1652 (in Vienna) and the magnificent "Self-Portrait With a Palette" (Iveagh bequest, Kenwood house, London), painted about ten years later, he analyzes his own moral and physical progress with the same objective compassion as is seen in his studies of other humble sitters, such as the "Old Man in an Armchair" (which entered the National gallery in 1957 from the duke of Devonshire's collection). Other outstanding single portraits are the "Jewish Merchant" (National gallery), the "Jan Six" (1654; in the possession of the sitter's family) and the hauntingly romantic "Polish Rider" (Frick collection, New York). Among the later portrait groups mention must be made of the superb painting of "The Board of the Clothmakers' Guild" (1662; Rijksmuseum). This group, known usually as the "Staalmeesters," or in English "The Syndics," stands supreme in its own category of Dutch group portraiture, as does "The Night Watch." Perhaps the crowning achievement of his career in portraiture was the even later "Family Group" (Herzog Anton Ulrich museum, Brunswick, Ger.). This displays all the qualities of his last manner—rich yet subdued colour harmonies, firm yet unobtrusive compositional structure, vigorous yet subtle brushwork—and is at the same time a tender expression of all that is meant by the family relationship. The same human understanding is to be found in the biblical subjects of this period. Some recall his style of about 1630, for instance "The Woman Taken in Adultery" (1644; National gallery) and the Elsheimer-like "Susanna and the Elders" (Berlin); but in the 1650s and 1660s he produced works of such unique depth of feeling that they elude comparison with any earlier master. Such are the "Peter Denying Christ" (1660; Rijksmuseum) and the profoundly moving "Return of the Prodigal Son" (Hermitage). Parallel with the development in his painted work is a similar deepening of human values in his etchings, of which the famous large plate of "Christ Healing the Sick" (the "Hundred Guilder Print"), of the 1640s, is possibly his supreme achievement in the medium. Finally, only the barest mention can be made of Rembrandt's incomparable drawings in pen or brush, or both, of which there are numerous examples in the principal collections on both sides of the Atlantic. *See* PAINTING: *The Netherlands: Rembrandt.* *See* also references under "Rembrandt" in the Index.

REMEMBRANCE DAY: *see* VETERANS DAY.

REMEMBRANCER, the name of certain English officials who from medieval times compiled the memoranda rolls and thus "reminded" the barons of the Exchequer of the business pending. There were at one time three clerks of the remembrance: the king's remembrancer, lord treasurer's remembrancer, and remembrancer of the firstfruits (*see* ANNATES). The latter two offices were abolished in 1833 and 1838 respectively. The king's remembrancer originally dealt with the recovery of penalties and debts due to the crown. After 1859 he was required to be a master of the Court of Exchequer. By the Judicature Act (1873) he was attached to the Supreme Court, after 1879 as a master. Since 1925 the office of king's remembrancer has been held by the senior master of the Supreme Court (Queen's Bench Division). The duties involved comprise functions connected with the selection of sheriffs, swearing in the lord mayor of London, and the Trial of the Pyx; *i.e.,* the annual examination of coins issued by the mint.

Remembrancer is also the title of an official of the corporation of the City of London, whose principal duty is to represent that body before Parliamentary commissions and at council and treasury boards.

(W. T. Ws.)

REMI (REMY, REMIGIUS), **SAINT** (d. *c.* 530), bishop of Reims and friend of Clovis (*q.v.*), whom he converted to Christianity, was appointed to his see in 459. Clovis, pagan king of northern Gaul, had married Clotilda (daughter of Chilperic, Christian king of Burgundy), whose attempts to convert him he resisted. According to legend, however, during his war against the Alamanni, he promised that he would be converted if Clotilda's God would grant him the victory. He was successful, and Clotilda, therefore, summoned Remi, who with St. Vaast instructed Clovis and baptized him in 496 or 506. Later his sisters and 3,000 men of his army also were baptized. Sources for Remi's life include only scattered references in Gregory of Tours and a few letters written by Remi and some contemporary bishops. Stories such as that of the dove that brought Remi a vial of oil from heaven for the baptism of Clovis, which was kept at Reims and used at the coronation of French kings, are later legends. His feast day is Oct. 1.

See A. Van de Vyver, "La victoire contre les Alamans et la conversion de Clovis," *Revue Belge de philologie et d'histoire,* 15:859–914 (1936), 16:35–94 (1937).

(J. N. G.)

REMINGTON, ELIPHALET (1793–1861), U.S. firearms manufacturer and inventor, was born at Suffield, Conn., on Oct. 28, 1793. In 1800 he traveled with his parents to the Mohawk valley, where they settled 20 mi. (32 km.) from Utica, N.Y. The elder Remington built a smithy and forge powered by a water wheel where he made horseshoes and agricultural implements. In 1816 young Remington built himself a flintlock rifle at his father's forge. It embodied no new inventions, but it was so remarkably accurate that the neighbouring sportsmen ordered similar guns from him, and within two years manufacture of sporting guns and rifle barrels became the main business of the forge. In 1828 Remington built a sizable factory beside the Erie Canal at the present site of Ilion, N.Y., and expanded his production. He and his son Philo pioneered many improvements in arms manufacture, including the reflection method of straightening gun barrels, the lathe for cutting gunstocks, and the first successful cast-steel, drilled rifle barrel in the U.S.

In 1847 Remington supplied the U.S. Navy with its first breech-loading rifle (Jenks carbine). In 1861, at the beginning of the American Civil War, the federal government placed large orders for small arms with Remington. He died on Aug. 12, 1861 in Ilion.

The Remington Arms Company is still a large manufacturer of sporting arms and ammunition. During the American Civil War and World Wars I and II it was an important supplier of small arms and ammunition to the U.S. government.

See Alden Hatch, *Remington Arms in American History* (1956).

(AL. H.)

REMINGTON, FREDERIC (1861–1909), U.S. painter, illustrator, and sculptor, noted for his realistic portrayals of the American West. He was born at Canton, N.Y., on Oct. 4, 1861, and studied at the Yale Art School and the Art Students League, New York. Thereafter he devoted himself primarily to illustrative work. He traveled widely, spending much time in the American West, and made a specialty of the subject matter for which he is best known—Indians, cowboys, soldiers, horses, and other aspects of life on the plains. He also published a number of books and articles, which served mainly as vehicles for his illustrations. During the Spanish-American War he was a war correspondent and artist. He died on Dec. 26, 1909, near Ridgefield, Conn. Remington was primarily a reporter, recording the image of the thing seen; his work is notable for its rendering of swift action and its accuracy of detail. The Remington Art Memorial, Ogdensburg, N.Y., contains a collection of his paintings, illustrations, and bronze statuettes.

See R. W. G. Vail, *Frederic Remington, Chronicler of the Vanished West* (1929); H. McCracken (ed.), *Frederic Remington's Own West* (1961).

REMIREMONT, a town of eastern France, *département* of Vosges, is situated on the left bank of the Moselle below its confluence with the Moselotte, 103 km. (64 mi.) SSE of Nancy by road. Pop. (1962) 9,020. The town is surrounded by forest-clad mountains. The abbey church, dating mainly from the 14th–15th centuries, has a crypt of the 11th century. The former palace of the abbesses (which now contains the *mairie* [town hall], the courthouse, and the public library) was rebuilt in 1752 and again in 1871. Some of the houses of the canonesses (17th and 18th centuries) remain. Remiremont is on a branch railway from Arches and Épinal. Industries include cotton spinning and weaving, embroidery, iron and copper founding, metal work, brewing, and the production of ready-made clothing. Its picturesque setting and old buildings have made it an attraction to visitors.

Remiremont (Romarici Mons) is named after St. Romaric, a companion of St. Columban of Luxeuil, who in the 7th century founded a monastery and a convent on the hills above the present town. In 910 an invasion of the Hungarians drove the nuns to Remiremont, which had grown round a villa of the Frankish kings, and in the 11th century they settled there. Enriched by the dukes of Lorraine, kings of France, and emperors of Germany, the ladies of Remiremont attained great power. The abbess was a princess of the empire and received consecration at the hands of the pope. The 50 canonesses were selected from the nobility. On Whitmonday the neighbouring parishes paid homage to the chapter in a ceremony called the "Kyrioles"; and on their accession the dukes of Lorraine, the immediate suzerains of the abbey, had to come to Remiremont to swear to continue their protection. The "War of the Escutcheons" in 1564 between the duke and the abbess ended in the duke's favour and terminated the abbess' power. The monastery and nunnery were suppressed during the Revolution.

REMONSTRANTS, those Dutch Protestants who, after the death of Jacobus Arminius, maintained the views associated with his name, and in 1610 presented to the states-general a "remonstrance" formulating their points of departure from stricter Calvin-

ism. The Remonstrants were assailed both by personal enemies and by the political weapons of Maurice, prince of Orange, and in 1618–19 the synod of Dort expelled them and declared Remonstrant theology contrary to Scripture. The movement remains, however, and its liberal school of theology has reacted powerfully on the state church and on other Christian denominations. *See* ARMINIANISM; DORT, SYNOD OF.

REMORA, a name given generally to fishes of the family Echeneidae, which are remarkable for having the spinous dorsal fin developed into a transversely laminated sucking disc, placed on top of the head; in a more restricted sense the name refers to a particular species, *Remora remora*, other species being given common names such as sharksucker (*Echeneis naucrates*), slender suckerfish (*Phtheirichthys lineatus*), whalesucker (*Remora australis*), etc. There are about 12 species, found in all tropical and temperate seas.

Remoras attach themselves to whales, porpoises, sharks, sea turtles and large fish; they are not, however, parasitic on these animals but are merely transported by them. They detach themselves and swim when searching for food, frequently bits that fall from the mouths of their "hosts." Each plate in the sucking disc can be elevated to produce a partial vacuum when it is attached to a flat surface.

Attempts to dislodge a remora by pulling merely make the attachment more firm; the fish can be detached, however, by sliding it forward. In some parts of the tropics fishermen have used remoras with a line attached to their tails to catch larger fish and sea turtles. (C. HU.)

REMSCHEID, a town of West Germany in the *Land* (state) of North Rhine-Westphalia (Nordrhein-Westfalen), Federal Republic of Germany, stands on a hill, 22 mi. (35 km.) NE of Cologne by road. Pop. (1961) 126,892. Situated in the heart of the Bergisches Land, Remscheid has interesting slate houses and a local museum. The neighbouring towns of Lennep and Lüttringhausen were joined to Remscheid in 1929. Lennep was the birthplace of Wilhelm Conrad Röntgen, the discoverer of X rays; and there is a Röntgen museum. Remscheid is connected to all parts of the Ruhr by railway.

The conurbation has a substantial iron industry and is the chief centre of the tool industry in Western Germany. Domestic and commercial kitchen and other equipment is made, and there is cloth manufacture.

REMSEN, IRA (1846–1927), U.S. chemist and university president, co-discoverer of saccharin, was born in New York City on Feb. 10, 1846. He was educated at the Free Academy (College of the City of New York; B.A., 1865), College of Physicians and Surgeons, Columbia University (M.D., 1867), and at the Universities of Munich and Göttingen (Ph.D., 1870). At the University of Tübingen (1870–72), where he was the assistant of Rudolf Fittig, he began the investigations into pure chemistry upon which his later fame was chiefly based. He became professor of chemistry at Williams College, Williamstown, Mass. (1872), and was one of the original faculty of Johns Hopkins University, Baltimore, Md., where he was professor of chemistry 1876–1913, director of the Chemical Laboratory 1876–1908, secretary of the Academic Council 1881–1901 and president of the university 1901–13. As president of Johns Hopkins he continued to emphasize the primary function of the university as a centre of research. He was president emeritus and professor emeritus 1913–27, during which time he traveled widely and worked on government pure food commissions. Remsen brought to Johns Hopkins many of the German laboratory methods and as a teacher he had many influential students. In 1879 he founded the *American Chemical Journal*, which he edited until it merged with the *Journal of the American Chemical Society* in 1914. In the first volume he described the preparation and properties of a new sweetening compound, subsequently known as saccharin (*q.v.*), which he and a pupil discovered. A long series of studies led to the discovery and enunciation of Remsen's law, concerning the prevention of oxidation in methyl and other groups. He wrote several textbooks of chemistry. Remsen died at Carmel, Calif., on March 5, 1927.

RENAISSANCE, a term commonly used in European historiography to denote, with widely different expansions and contractions of significance, a "rebirth" (Fr. *renaissance*, from Ital. *rinascenza*, more commonly *rinascimento*) or "revival" of learning or of the arts, supposed to separate the Middle Ages and the modern period. To those who interpret history in terms of modern progress, the Renaissance was the first milestone along the primrose path to be marked out subsequently by the voyages of discovery; by the Reformation; by the scientific revolution of Vesalius and Copernicus, Kepler and Galileo, Huygens and Newton; by the Industrial Revolution; by the French Revolution; by parliamentary reform in Great Britain; by the rapid exploitation of material resources in the United States; and by imperialistic expansion in Asia and Africa. Events of the 20th century, however, have done much to discourage this progressist interpretation of history, with its doctrine of steady human improvement and its emphasis on the supreme importance of European civilization and of a brief period of human activity which was limited to the inhabitants of Western Europe. At the same time the reassessment of the Middle Ages by scholars who had made real research into the documents of that period called into question many of the notions that had accumulated round the word Renaissance. In this article an attempt is made to explain the Renaissance as the "revival of learning," that is, of Latin and Greek classical literature, in Italy from the middle of the 14th century to the early years of the 16th; and to dispel some of the misconceptions long prevalent about the period.

Readers wanting to be informed on the general history of the Western world from the 14th to the 16th century are referred first to the article EUROPE: *History* and to MIDDLE AGES. For the immediate background of the Renaissance *see* ITALY: *History* and the separate articles on the states and dynasties therein mentioned. The historical sections of the articles on other European countries are also relevant.

The development of imagination and sensibility during the period can be studied in the articles on the vernacular literatures of Western Europe. Of especial importance, however, because of the period's distinction in the fine arts, are the articles PAINTING; RENAISSANCE ARCHITECTURE; RENAISSANCE ART; and SCULPTURE. It was largely on the recognition of the magnificent achievement of the period's artists and architects that the notion of the Renaissance as a miraculous age was built up; and indeed it is in the fine arts that the positive influence of the revival of antiquity first becomes discernible outside the field of scholarship. Critics of the fine arts, of vernacular literatures, and of the drama, however, use the expression Renaissance in extended senses which make it necessary to omit their subjects from this article.

Original Meaning and the Growth of Misconceptions.—The original meaning of the Italian Renaissance of the 14th and 15th centuries—for those who actually participated in it, and through subsequent centuries down to the vernacular classicism of French literature of the 17th century and of English literature of the 18th—was the revival of classical Latin and Greek literature, or, more strictly speaking, belles-lettres, by Petrarch and his followers the humanists. Petrus Ramus (*q.v.*), in an oration of 1546 attacking the Aristotelian logic of the scholastic philosophers, drew a vivid contrast between education at Paris in his own time and education 100 years before. Suppose, he said, that a master of a century ago could return now, what progress he would find, how amazed he would be! He would be as astounded as one who, rising from the depths of earth, should gaze for the first time on sun, moon, and stars. Then he could have heard no one speak save in an inept and barbarous fashion; now he would find countless persons of every age speaking and writing Latin correctly and ornately. Then no one could read Greek; now men not only read it but comprehend it thoroughly. As grammarians, orators, and poets, he used to have to put up with Alexander of Villa-Dei, Facetus and the *Graecismus*; in philosophy, with Scotists and with the followers of Petrus Hispanus; in medicine, with the Arabs; in theology, with I know not what upstarts. Today he would hear

Terence, Caesar, Virgil, Cicero, Aristotle, Plato, Galen, Hippocrates, Moses and the prophets, the apostles and other true and genuine messengers of the gospel—and indeed voices in all languages!

Except for its closing allusions to vernacular translations of the Bible, this passage, though none too accurate, well expresses the original restricted significance of the Renaissance as a purifying of Latin diction and grammar, a revival of Greek and a return from medieval compilations to the old classical texts. Already before Ramus and 1546, however, this talk of a resuscitation of liberal studies had become hackneyed and had furthermore been extended to most inappropriate fields. For instance, when the astronomical Alphonsine tables, dating in fact from the second half of the 13th century, were about to be printed in 1492, an astrologer of Olmütz (Olomouc) wrote to their editor, J. L. Santritter, congratulating him on this and himself for living in such a time, when learning was being revived after long neglect. In reply Santritter agreed that all good arts were not only reviving but already in bloom, so that soon modern times would equal the golden age of ancient Rome. Yet actually the occasion of their rejoicing would seem a revival of 13th-century astronomy. Similarly, Alessandro Achillini in 1504, in the preface to a recent work on chiromancy and physiognomy, said that these subjects had remained in darkness for many years past. Similarly again, it was said that Antiochus Tibertus of Cesena, whose *Three Books of Chiromancy* were first printed in 1494, revived the magic art which had been forgotten since the time of Peter of Abano (1250–1315?); Vesalius referred to anatomy as reborn in his *Fabrica* of 1543 and was silent as to his predecessors; and Abstemius represented Pope Paul III (d. 1549) as restoring astrology after many past centuries of darkness and disrepute, barbarism and sordid squalor.

At the zenith of the Enlightenment (*q.v.*), Voltaire in the introduction to his *Siècle de Louis XIV* (1751) selected the Renaissance as the third of the great ages of mankind—to follow the period from Pericles to Alexander the Great in ancient Greece and the age of Julius Caesar and Augustus in Rome and to precede the age of Louis XIV in France and Western Europe. By the 19th century the old and limited conception of the Renaissance was regarded as wholly inadequate. The French historian Jules Michelet defined it as "the discovery of the world and of man"; and Jacob Burckhardt, in his once influential work *Die Kultur der Renaissance in Italien* (1860; Eng. trans., *The Civilisation of the Renaissance in Italy*, 1878 and later editions), made this theme the subject of the fourth part, which followed immediately after its scholarly third part on "The Revival of Antiquity." To John Addington Symonds and Walter Pater the vaguest or the most potentially comprehensive uses of the term Renaissance were the most acceptable. Symonds, for example in his *Renaissance in Italy* (1875), claimed that "in many senses we are still in mid-Renaissance"; and then after an impressive catalogue of achievements in every branch of desirable activity—the arts, literature, philosophy, theology, science, government, law, exploration, and technical invention—could resume:

> Yet neither any one of these answers separately, nor indeed all of them together, could offer a solution of the problem. By the term Renaissance, or new birth, is indicated a natural movement, not to be explained by this or that characteristic, but to be accepted as an effort of humanity for which at length the time had come, and on the onward progress of which we still participate. The history of the Renaissance is . . . the history of the attainment of self-conscious freedom by the human spirit manifested in the European races . . . The arts and the inventions, the knowledge and the books which suddenly became vital at the Renaissance, had long been neglected on the shores of the Dead Sea which we call the Middle Ages. It was not their discovery which caused the Renaissance. But it was the intellectual energy, the spontaneous outburst of intelligence, which enabled mankind at that moment to make use of them. The force then generated still continues, vital and expansive, in the spirit of the modern world . . . . . The mystery of organic life defies analysis.

At this rate, Petrarch was soon being called the first modern man of letters, not merely the father of humanism; and Erasmus, who lived when the classical revival in Italy had already culminated, was called the first modern man. Alternatively the magical metamorphosis of medieval man or classical humanist or scholar into *homo modernus* was postponed until Elizabethan England, which the *Boston Transcript* of Feb. 17, 1926, could describe as a "period that witnessed the birth pangs of most that is worth while in modern civilization and government." Before proceeding to contest misconceptions in detail, some account must be given both of the real progress made before the classical revival and of the revival as it really was.

The Civilization of the Middle Ages.—A chief reason for regarding the Italian Renaissance as the first milestone of modern progress was past misestimates of the preceding medieval period, which was variously stigmatized as blank or dark; disorderly, confused, and chaotic; unsanitary and dirty; primarily ecclesiastical and superstitious; in bondage as to thought; quaint, outlandish, and incomprehensible to the modern mind. By the middle of the 20th century such views had been entirely discredited by historians. The 13th century, indeed, reached a high point of civilization, to which later centuries are largely indebted for representative institutions, for municipal organization and town life, for economic development, for the first modern maps, for technical invention and scientific progress, for vernacular literature, and for Gothic art. Activity in these fields continued into the 14th century: Dante lived till 1321, Giotto till 1337; Pietro dei Crescenzi finished his important work on agriculture *c.* 1305; Lancilotto Malocello reached the Canaries in 1312; Marsilius of Padua in 1324 completed the *Defensor pacis*, Thomas Bradwardine in 1328 his work on the proportion of velocity, in which by an exponential function he applied mathematical method in physics; and in 1324 also the *Jeux floraux* of the successors of the troubadours were organized at Toulouse.

There had been occasional instances of lovers of pure Latin literature throughout the Middle Ages, notably in France; and by Petrarch's time groups of scholars in Padua and Verona were already taking an active interest in the ancient writings. It was not until the 14th century, however, that a general movement for the investigation of that literature was brought about in Italy, chiefly by Petrarch. The reasons for the delay may be explained briefly. After the breakup of the Roman Empire in the West and the Arabic conquest of most of the Mediterranean world, Arabic became the dominant language from Persia to the Spanish Peninsula. Ancient Greek works of science, medicine, and astrology were translated into it and led to further writings in Arabic in those fields; but the Arabs, who already possessed fine poetry of their own, were not interested in the translation of pure literature from the Greek. Similarly the Christian West, where Latin became the universal language of scholars, relied on what was available in Latin for its knowledge of the pure literature of the ancients. In the 12th and 13th centuries, however, the Christian West engaged itself in a great movement of translation of scientific,

FIG. 1.—RELIEF FROM THE TOMB OF POPE SIXTUS IV, BY ANTONIO POLLAIUOLO, 1493, IN THE VATICAN

"Philosophia" is reading from Aristotle's *Metaphysics*; the book on the lectern is inscribed with the opening words of his *Physics*

medical, astrological, and alchemical works from both Greek and Arabic, and these were naturally studied and commented on in the universities that developed in the same period. In these universities Roman law was also studied, and a new living Latin was spoken, adapted to contemporary needs and environment. Though the plots of Greek story, from the Trojan War to the conquests of Alexander the Great, were utilized even in vernacular literature, they were generally derived from secondary Latin sources, and the medieval romances introduced many changes in the story and depicted the ancient heroes as feudal lords or knights. The way was therefore open for a more direct approach to ancient Greek literature and for a reappraisal even of classical Latin literature from a human and literary standpoint; namely for humanism as against the scholasticism (*q.v.*) of the medieval universities.

Petrarch.—The advent of humanism must be seen against the background of the unfortunate events that distinguished much of the 14th century from the glorious 13th. The Hundred Years' War (*q.v.*) between France and England began; the Black Death (*q.v.*) ravaged Europe; and from the Italian point of view the migration of the papacy from Rome to Avignon in 1309 was also to be deplored. Petrarch (*q.v.*), who lived from 1304 to 1374, was conscious of a great social change for the worse since his student days at Montpellier and Bologna. In Rome, he thought, all was cold and lifeless; the kingdom of Naples was ruined since the death of King Robert in 1343; the Lombard cities and likewise Pisa, Siena, Arezzo, and Perugia were in decline; even Venice, though prospering by comparison with the others, was less prosperous than it had been. The neighbourhood of Avignon, where he had himself once roamed over the hills by night, was now infested by wolves and robbers. The Netherlands and lower Germany, once so rich, were in ashes, with hardly a house left standing outside the city walls. And in Paris itself the clash of arms had replaced the sound of disputants.

BY COURTESY OF THE BIBLIOTECA NAZIONALE S. MARCO

FIG. 2.—MANUSCRIPT PAGE OF PETRARCH'S DE REMEDIIS UTRIUSQUE FORTUNAE, COMPLETED 1366, WITH PORTRAIT OF PETRARCH IN THE ILLUMINATED INITIAL. IN THE BIBLIOTECA NAZIONALE S. MARCO

It was in the midst of such catastrophic change that the Italian Renaissance was born. In his youth Petrarch had written love sonnets in Italian and been crowned poet laureate by King Robert of Naples in Rome in 1341; but in his later years he fell so much in love with classical antiquity that he deigned to write only in Latin, addressing letters to Cicero and to other ancients whom he admired, or to posterity, as well as to his living friends—who included popes and emperors, since he had traveled widely and gone on public embassies. Also, his letters, not to mention his other works in Latin prose and verse, were circulated widely to other admirers of his style and content, both of which he attempted to make classical. He thus stirred up an interest in the cultivation of classical literature primarily for its literary and human side, its personal, emotional, and rhetorical features. It was this attitude, with the activity ensuing from it, that came to be known as humanism.

Burckhardt admired Petrarch's writings for their "marvelous abundance of pictures of the inmost soul," though he recognized "much that is forced and artificial" in the poetry. On the other hand James Russell Lowell (*Among My Books*) blamed Petrarch as providing the first instance of sentimentalism—of which Lowell held the classics to have been free—and regarded him as "an intellectual voluptuary, a moral dilettante." A third estimate, by Edward Williamson (*Romanic Review,* 1959), is that the "impenetrable barrier" of Petrarch's rhetoric precludes intimacy between himself and the reader. Petrarch himself recognized that his studies and interests had changed since his youth and was glad of it; but he added that this change for the better was as nothing compared to the change for the worse in Western Europe.

The Achievement of Italian Humanism.—Petrarch's example stimulated a movement that went on through generations. Of his immediate collaborators, the most important was Giovanni Boccaccio (*q.v.*), who did much to establish the early leadership of Florence in the movement. A supremely successful seeker after Latin manuscripts, he also secured the appointment of Leonzio Pilato (d. 1367) to teach Greek there. Under the patronage of such men as Coluccio Salutati (1331–1406), chancellor of the *signoria* from 1375, and of Cosimo de' Medici (*see* MEDICI), humanism in Florence continued to prosper, and Florence profited largely from the travels undertaken in search of antiquities by such men as Poggio (*q.v.*) and Cyriacus (*q.v.*) of Ancona. The latter began life as a merchant but finally became a leading collector of ancient remains—objects of art and coins as well as manuscripts—and left several volumes of transcribed inscriptions, unfortunately destroyed by fire in 1514. Other Italian cities also played their part. Milan under the Sforza dynasty maintained Francesco Filelfo (*q.v.*) for more than 30 years. Naples, where King Alfonso I the Magnanimous (Alfonso V of Aragon) was especially benevolent to humanists, long sheltered Lorenzo Valla (*q.v.*) and Antonio Beccadelli, otherwise known as Panormita (1394–1471). After the final return of the lawful papacy (1377), Rome likewise became a humanist centre.

The humanists' efforts led to a better comprehension of classical Latin and of ancient civilization. New grammars and dictionaries were composed; classical philology and literary criticism gradually evolved; and books were written on classical history and antiquities, geography, and mythology. With regard to the pursuit of Latin manuscripts and classical inscriptions by the humanists, it should be remembered that, in the days before printing, men of learning—astrologers, physicians, or legists, for instance—were all accustomed to making copies for themselves of particularly interesting works that they encountered; and that Petrarch's copying of rare works for his own library was thus not unprecedented. Moreover, the classical manuscripts studied by the humanists were copies made at some time in the Middle Ages from earlier texts. The humanist might claim to have rescued the work from oblivion in some monastic library where no one had read it for years. But when he came to make his will he might well leave his library for safekeeping to some other monastery; otherwise the library might be dispersed on his death, as Petrarch's was. Even so, the copying of one humanist's copy by others—or even by whole workshops of scribes specially engaged for the purpose—soon led to an immense proliferation of texts in manuscript. The recording of inscriptions preserved texts that might otherwise not have survived the decay or demolition of the monuments on which they were engraved. Two Veronese epigraphers of the late 15th century did valuable work: Felice Feliciano, who made a study of the geometric construction of letterings on ancient inscriptions; and Fra Giocondo (baptized Giovanni; d. 1515), who was also celebrated as an architect and as a military engineer.

It was once held that the fall of Constantinople to the Turks in 1453 drove Greek manuscripts and scholars west and so caused the Italian Renaissance. On the contrary, it was Italian humanists who from 1393 onward took the initiative in visiting Constantinople to learn Greek and to bring Greek manuscripts back with them. Coluccio Salutati had advised Jacopo Angelo to look for lexicons, historians, and poets and, especially, for manuscripts of Homer, Plato, and Plutarch. Guarino da Verona (d. 1460), later famed as a humanist educator, returned in 1408 with more than 50 manuscripts. Giovanni Aurispa (*c.* 1375–1459) brought back 238 manuscripts, filled almost entirely with Greek works of pure literature, in 1422–23. Filelfo, after nearly seven years in the Venetian legation at Constantinople, came back in 1427 with about 40 authors. Such works were at first known chiefly through the inferior Latin translations that were made of them. Conversely, native Greeks visited the West before 1453 as Byzantine envoys or to attend church councils: both George Gemistus Pletho and

John Bessarion (*qq.v.*) first arrived in this way, at the time of the Council of Ferrara-Florence (1438–39). Some Greeks were recalled as lecturers and, like Manuel Chrysoloras (*q.v.*) at Florence in 1396, aroused interest in Greek. Others were already refugees, for the Turks had overrun much of the Balkan Peninsula before they took Constantinople. These Greeks who came to Italy usually taught their language or made translations into Latin, but they rather outlived their welcome and were not esteemed very highly. Their interests were often scholastic rather than humanistic. Bessarion defended Plato against the Aristotelianism of George of Trebizond (1395–1484); and Gemistus Pletho awakened some interest in Neoplatonism, which the Florentine Marsilio Ficino (1433–99) carried further.

Few Italians were Hellenists to the extent of doing much more than translate a single Greek work into Latin. Politian (*q.v.*), who lived till 1494, in the preface to his Latin translation of Homer, pictures the young patricians of Florence as speaking Greek so fluently that one would think oneself in the streets of ancient Athens; but this flattery may be somewhat overdrawn. In Venice the circle of Aldus Manutius (*q.v.*), founder of that Aldine press which from the 1490s produced such famous editions of the classics, tried to talk Greek, imposing the fine of a small coin for failure to do so. The first printed book in Greek was the grammar of Constantine Lascaris (1476), for which Demetrius of Crete cast the type. Original compositions in Greek by Italian humanists before 1500 were few, the chief contribution being Politian's Greek epigrams. Politian also surpassed the others in Latin diction; he was a distinguished philologist; and his *Orfeo,* a dramatic poem in the vernacular, is the seedling of Italian opera.

With the introduction of printing (*q.v.*), humanistic texts poured from the press, though it should be borne in mind that scholastic texts did so likewise at the same time. These early printed books retained many characteristics of the medieval manuscripts, including contractions and abbreviations which make them hard to read; but some incunabula, as books printed during the 15th century are called, are also beautiful works of art. Usually made from a single manuscript and very faithful to their source, the classical texts printed by the humanists are not critical editions in the modern sense involving a collation of numerous manuscripts; but modern critical editions have profited by the textual criticism of the humanists (the 15th-century manuscript of Lucretius in the Laurentian library, for instance, is of great value for the final determination of the text). The *Castigationes Plinianae* of the Venetian Ermolao Barbaro (1454–93) were still highly valued in 1875 as "of incredible erudition and singular sagacity." Barbaro moreover suggested many of the coinage problems which were considered later in the French scholar Guillaume Budé's *De asse.*

Special Characteristics of the Italian Humanists.—Humanism made little headway at the Italian universities; even Lorenzo de' Medici gave up the attempt to develop a university in humanist Florence and returned the institution to Pisa. Humanists more often found employment as secretaries or orators for governments; and in this capacity they took their time in composing dispatches or speeches, for fear lest they might be guilty of some barbarism or defect of Latinity. In their literary style they were inclined to indulge in sententious utterances and to concern themselves with reviving a lost art of eloquence. Lorenzo Valla's *Elegantiae linguae latinae* (1444), on the niceties of the Latin language, with specific criticism of the Latin style of some of his fellow humanists, ran through 60 editions between 1471 and 1536. An effect of this preoccupation was that, as the remote classical past was recovered, the immediate medieval past was neglected and forgotten, and medieval Latin came to be regarded as barbaric. By thus substituting an artificial, bookish, and dead language for the living, spoken Latin of the Middle Ages, the humanists to some extent defeated their own purpose, and their work degenerated into antiquarian scholarship. On the other hand they aroused such enthusiasm for relics of antiquity that contemporary artists sometimes tried to pass their own work off as ancient, so as to command a higher price; and some Italian humanists were themselves guilty of literary forgeries, ascribing compositions of their own to antiquity. Thus Leonardus Dathus (Leonardo Dati), who died bishop of Massa in 1472, pretended to have discovered and translated into Latin a work by Caelius Vibenna in ancient Etruscan on the deeds of King Porsena and the Clusini; and he dedicated his translation to Pope Pius II, the former humanist Aeneas Sylvius Piccolomini. Likewise Joannes Annius of Viterbo (Giovanni Nanni; *c.* 1432–1502), who had been trained in Greek and Hebrew by Dominicans and was closely associated with popes Sixtus IV and Alexander VI, faked the lost works of the Roman historian Fabius Pictor and of the Babylonian priest Berossus.

The Italian humanists wrote on the dignity of man, on human excellence and human felicity, and on learned men from an aristocratic rather than from a democratic outlook. Cicero had used the word *humanitas* not only in the sense of human kindness but also to mean refinement of education and taste, good breeding, and mental cultivation. The humanists' concern was with their learned and noble contemporaries, not with the masses or populace. The *virtù* that they admired was an excellence transcending social considerations, an ethic ideal for the individual, not for the many.

Some of the humanists were clergymen; others were sincerely

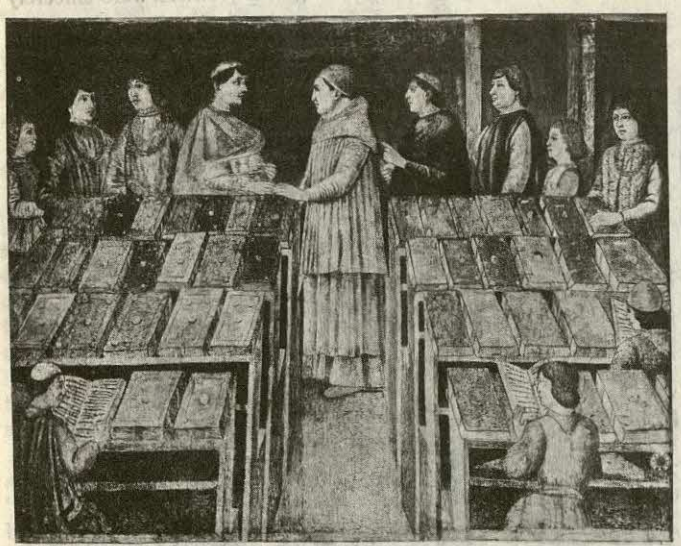
religious; practically all of them conformed outwardly to Catholicism. The pagan and worldly influence of classical Latin literature, however, tended to encourage a critical and skeptical attitude. This too may be illustrated by Lorenzo Valla. His *De voluptate* (1431) was a frank defense of sensual pleasure; and in 1439, while he defended freedom of the will, he attacked the Aristotelian logic of the scholastics. Whereas most humanists treated history as a mere branch of literature, Valla in 1440 employed historical and textual criticism to impugn the Donation of Constantine, which represented the first Christian emperor as surrendering the West to the pope, and to attack the legend that the Apostles' Creed had been composed independently by each apostle. His notes on the Latin text of the New Testament foreshadowed Erasmus' edition of the Greek text. A work in which Valla set spontaneous virtue above monastic vows (not printed until 1869) looked forward to the Protestant Reformation.

Valla's subversive attitude brought him occasionally into trouble with the church, but he emerged unscathed and finally received an appointment in the Roman *curia* under Nicholas V, who as Tommaso Parentucelli had himself been known as a humanist before he became pope in 1447. The scandalous *Hermaphroditus* of Beccadelli incurred ecclesiastical censure for its complaisant description of licentious practices, but the favour of secular rulers protected the author. In Rome, however, the humanist academy of Julius Pomponius Laetus (*q.v.*) was suppressed by Pope Paul II in 1468. Its assiduous resuscitation of pagan Roman customs and its enthusiasm for the ancient Roman republic gave offense; and some of its adherents, including Platina (Bartolomeo Sacchi da Piadena; 1421–81), were suspected of conspiring against the life of the pope, who had dismissed a number of humanists from the chancery in which Pius II had installed them as *abbreviatori* or clerks.

Academies or literary societies and coteries were common among the humanists. The academy founded by Beccadelli in Naples in 1442 became the Accademia Pontaniana, taking its name from that of his successor, Giovanni Pontano (*q.v.*). The Accademia Platonica, which Cosimo de' Medici founded in Florence, was the last refuge of Pico della Mirandola (*q.v.*). Among themselves, however, the humanists were strongly addicted to controversy, not only on points of scholarship but also on general issues and on matters of taste or subjective opinion. Such quarrels were conducted with extreme virulence. Poggio, for example, was involved in widely publicized disputes with Filelfo on Florentine affairs, with Guarino on the comparative merits of Scipio Africanus and Julius Caesar, and with Valla on the style of his Latin; and Valla had notable controversies of his own.



MANSELL-ANDERSON

The Migration of Humanism to Other Countries.—Humanism spread to Germany in the last quarter of the 15th century and the first quarter of the 16th. In England, William Grocyn and Thomas Linacre (*qq.v.*) had been pupils of Politian; and both John Colet and Thomas More (*qq.v.*) were influenced in their Christianity by Italian humanism. In France, Robert Gaguin (*c.* 1425–1501), who also concerned himself with the nonclassical history of France, was the leading Latinist in the closing 15th century; and Guillaume Budé (*q.v.*) was a pioneer numismatist and Hellenist in the early 16th. Antonio de Nebrijah (*q.v.*) took Italian humanism to Spain; and his pupil Juan Luis Vives (*q.v.*) has been grouped with Budé and with Erasmus as one of the triumvirs of the republic of letters in the early 16th century. In these countries the movement was associated with the universities rather than disassociated from them as in Italy; and the non-Italian humanists interested themselves in their particular national history as well as in classical history. Moreover, a man of learning could sometimes acquire the title of humanist simply by virtue of a slur or two against scholasticism to be found in his writings, or by not being a very reactionary monk or theologian. There were, however, better Greek and Hebrew scholars north of the Alps soon after 1500 than there had been in Italy in the 15th century.

MANSELL-ALINARI

FIG. 5.—PICO DELLA MIRANDOLA, A LATE 15TH-CENTURY PORTRAIT BY AN ANONYMOUS MASTER; IN THE UFFIZI GALLERY, FLORENCE

Desiderius Erasmus (*q.v.*), a native of the Netherlands who visited Italy, France, England, and Switzerland and whose writings circulated widely in Spain, may be regarded as the kingpin of the movement in these lands and as the leader in what has been called the Christian Renaissance in distinction from the Italian Renaissance. If, in the 18th-century words of Alexander Pope, "the monks finished what the Goths begun," it was Erasmus who

> Stemmed the wild torrent of a barbarous age
> And drove those holy vandals off the stage.

Yet Erasmus had his blind spots. He was ignorant alike of the great writers of the 13th century and of the Greek writers and culture of the 5th and 4th centuries before Christ. He scorned modern languages and nationalism and had little interest in natural science. He hardly mentions the New World or the fine arts.

Italy's hegemony in the world of classical learning may be regarded as having been brought to an end by the sack of Rome during Clement VII's papacy by the soldiers of the constable duc de Bourbon in 1527—a by-product of the wars between Francis I of France and Charles V, Holy Roman emperor and king of Spain. Though Clement's successor, Paul III, raised the humanists Pietro Bembo (*q.v.*) and Jacopo Sadoleto (1477–1547) to the cardinalate, his pontificate was chiefly important for the opening of the Counter-Reformation at the Council of Trent. (*See* further CLASSICAL SCHOLARSHIP.)

Humanist Political and Economic Thought.—In general the humanists, from Petrarch to More and Erasmus, if they were cognizant of any alteration in political and economic conditions or in moral and social values, regarded it as for the worse. The political and economic thought of schoolmen and canonists; or of the legist Bartolus (1313–57), whom Valla criticized; or of Nicole Oresme (d. 1382); or of Wycliffe (d. 1384); or of Archbishop Antonino of Florence (d. 1459), who dared to defy the Medici by posting on the cathedral door a message written in his own hand urging the citizens to retain the secret ballot—the thought of all these surpassed that of the Italian humanists before 1500. Some credit, however, may be given to Lippo Brandolini (d. 1497) for the work of comparison between a republic and a kingdom, dealing with the relative merits of the Florentine and the Hungarian sys-

tems of government (with occasional allusions to other states of Europe), which he began at the court of the Hungarian king Matthias Corvinus in the winter of 1489–90 and completed in Florence. It is in the 14th and 15th centuries that a purely economic point of view is expressed for the first time in written records, such as commercial bookkeeping and arithmetic and treatises composed by businessmen for businessmen; but these practical writings in the vernaculars had no connection with classical Latin, humanism, or the revival of antiquity.

The humanists were likely to approach political and economic problems from a literary and antiquarian angle and were lacking both in basic principles and in the logic to evolve a consistent and systematic treatise or philosophy from them. Also many of them were in the service of despots, who found them better publicists than university faculties were, and less independent. The humanists might desire the reform of social ills, but they seldom succeeded in bringing it about. Niccolò Machiavelli (*q.v.*), the greatest political thinker of the Renaissance period, was saturated with classical history and with the culture of the humanists, but he stands quite apart from them for the realism of his approach; and his *Principe* (1513), which he dedicated to the Medici pope Leo X, was not published in his lifetime.

In law such classicists as Andrea Alciati (1492–1550) and Jacques Cujas (*q.v.*) affected style and local colour more than substance.

Contemporary Technology and Science.—The fact that Valla's treatise on novelties unknown to the ancients has not survived indicates that his age was more interested in classical antiquity than in recent inventions. Of the three inventions that used to be associated with the Renaissance, namely the mariner's compass, gunpowder, and printing with movable types, only the last can still be ascribed to the period, since the other two are now known to date back at least to the 13th century. The introduction of printing into Europe, however, took place north of the Alps and cannot be shown to have had any connection with the classical revival—though insofar as judgments came later to be formed merely on the basis of what had been printed, the advantage that the humanists took of the invention served to induce a neglect of the medieval period, whose records were left in manuscript.

Italian humanism produced relatively little of scientific or philosophical importance from its investigation of the classical past: Leonardo Bruni (*q.v.*) of Arezzo said that the subtleties of arithmetic and geometry were not worthy of a cultivated mind. In any case, most available works of Greek science had already been translated into Latin before 1300. Ptolemy's *Cosmographia* or *Geography*, however, had remained untranslated among the 33 Greek manuscripts in the library of Pope Boniface VIII, probably because Arabic geographers and Latin travelers to the Far East had corrected and supplemented it on many points, and the translation of it in 1406 by the humanist Jacopo Angelo had a regrettable sequel. So great was Ptolemy's reputation as an astronomer (his *Almagest* had been translated in the 12th century, from both Greek and Arabic), and so intense was humanist devotion to classical authors, that the obsolete *Cosmographia* was often followed by navigators of the age of discovery and even more often in maps of the 16th century. At first it was hoped that new manuscripts and translations of Hippocrates and Galen would free medicine from the Arabic influence of Avicenna and others, but they made little real difference.

The preoccupation of the humanists with belles-lettres and with the fine arts was followed in the 16th century by the preoccupation of Europe with religious movements—the Reformation and the Counter-Reformation. There resulted a widespread neglect not only of the earlier scientific progress of the 13th and of the first half of the 14th century but also of the minor scientific activity that had been pursued at Venice and elsewhere concurrently with the Renaissance. Thus arose the notion that modern science originated at the earliest with Copernicus and Vesalius in the 1540s, or perhaps as late as the 17th century.

Venice, the most stably governed of the Italian states, had been a centre of scientific and technological activity that bore no relation to humanism. In 1415, after travel elsewhere, Benedetto Rinio had settled there and composed a herbal, richly illustrated by the painter Andrea Amadio, which was kept for a time at a shop in the street of the dealers in spices and which is now preserved in the library of St. Mark's —together with the rare Greek manuscripts that Bessarion left to Venice, as the safest asylum for them, under his will of 1468. Leonardo of Bertipaglia, employed by the government of Venice as lecturer on surgery at the University of Padua in the 1420s, possessed great manual dexterity and ingenuity and wrote with gusto. Sante Ardoini of Pesaro wrote his work on poisons at Venice in 1424–26, full of allusions to what he had seen or heard in Venice and to his medical practice there. Giovanni da Fontana, a citizen of Venice, wrote in 1440 and thereabouts on instruments, measurement and mechanical advance, military and hydraulic engineering, distant lands and contemporary map making. All these authors display an independence, confidence, and present experience which is in refreshing contrast to humanist studies of ancient literature and civilization. Outside the Venetian zone, Giovanni Bianchini composed his astronomical tables at Ferrara in the middle years of the 15th century, and the Florentine Paolo del Pozzo Toscanelli (1397–1482) was one of many observers of the appearance in 1456 of what later came to be known as Halley's Comet.

Nor was such activity confined to Italy. There survives, by an anonymous author and from a place unknown, a daily record of the weather from Aug. 31, 1399, to June 25, 1401, fuller than any known before, with observations in the morning, afternoon, and evening, or even through the night, and distinguishing wind aloft from wind near the ground. In 1410 the Frenchman Pierre d'Ailly wrote the *Imago mundi* used later by Columbus. Johann von

Gmunden was active at Vienna early in the 15th century in astronomy and in mathematics, in which he was followed by Georg Peurbach (Peuerbach or Purbach; 1423–61) and by Johann Müller (*q.v.*) of Königsberg, generally known as Regiomontanus. Nicholas of Cusa wrote on static experiments in 1440. Of all these men, in or out of Italy, only Peurbach and Regiomontanus can be closely associated with the Italian Renaissance. They had taught Latin classics at Vienna, and Bessarion turned over to them the composition of an epitome in Latin of Ptolemy's *Almagest* (this epitome was the only version of that work to be printed before the middle of the 16th century). Peurbach was astronomer-astrologer to László V of Hungary; and Regiomontanus, after his astrological selection of a favourable moment for the foundation of the University of Pressburg (Pozsony, Bratislava) had not assured that university's success, spent some time at the humanistic court of Matthias Corvinus, arranging the royal collection of Greek manuscripts.

The notebooks of Leonardo da Vinci (*q.v.*), who is often regarded as the example par excellence of the universal genius and all-round man of the Renaissance, have been held to forecast subsequent inventions, but they are found also to have copied a good deal from previous authors. He did important work of his own, however, on anatomy. But in any case Leonardo belongs with the artists and architects, not with the humanists.

Conclusions.—In the light of the foregoing, some of the claims made for the Renaissance in the expansive senses of the word can now be examined. If Michelet's "discovery of the world" be taken to refer to the voyages of discovery of Columbus, Vasco da Gama, and others, it should be said that these voyages had almost no relation to classical literature but were the medieval culmination of a medieval widening of the world and "dawn of modern geography" since the 13th century. Moreover, against the opening up of new continents and sea routes must be set the contraction of Europe in the face of the Turkish advance to the middle Danube, with Greece itself overrun in the process. If the phrase is taken to indicate appreciation of nature, it can be discarded because such appreciation is found to a high degree both in medieval literature and in Gothic art.

When Petrarch's ascent of Mont Ventoux is cited as the first example of a man's climbing a mountain for the sake of the view, the fact that the Parisian schoolman Jean Buridan had visited Mont Ventoux before Petrarch and had given data as to its altitude is overlooked; and Gertrud Stockmayer traces the feeling for nature in Germany back to the 10th and 11th centuries and records various ascents and descriptions of mountains from that period (*Über Naturgefühl in Deutschland im 10. und 11. Jahrhundert,* 1910).

Intensive reading of the pagan classics would undoubtedly give one a different slant on life from that given by the reading of Arabic poetry or the perusal of Christian volumes. But such acquired characteristics would scarcely be transmitted to one's posterity unless they kept up such reading. Moreover, it is to be remembered that reading of the classics was usually combined with the reading of the Bible, saints' lives, books of hours, Church Fathers, and medieval chronicles and even romances. It was not the whole story, but rather a new ingredient added to an old compound, or increased in amount over what had been previously absorbed in the grammar school.

Did the Renaissance promote a discovery of man in the sense of more marked individuality and personality, or were there more "complete men" in the 15th century than in the Middle Ages, as Burckhardt asserted? Apart from the examples of marked personality that occur continually in the period lying between antiquity and the Renaissance, individuality itself and its problems (the *haecceitas* of Duns Scotus, for instance) were frequently discussed by the medieval schoolmen, whereas not even the word is found in classical Latin. And against the claim for "completeness" may, on the one hand, be cited the many-sided men of the Middle Ages, such as Ramon Llull, and, on the other, may be asked how completeness is to be reconciled with that absence of moral or social sense which so often characterized the pursuit of *virtù,* or individual excellence.

As for the first modern man or the beginning of modern ways, it should be remembered that the men before the Renaissance regularly spoke of themselves as "moderns" (*moderni*). The modern spirit has been detected in St. Francis of Assisi as well as in Petrarch and Erasmus. This modern spirit was rampant at Paris in the 12th century and was satirized by John of Salisbury in his *Entheticus* as follows:

> On all sides they clamour:
> Of what interest to us are the sayings or deeds of the ancients?
> We are self-taught; our youth has learned for itself.
> Our band does not accept the dogmas of the ancients;
> We do not burden ourselves in following their utterances.
> Rome may cherish the authors of Greece.
> I dwell on the Petit-Pont, and am a new authority in arts.
> It may have been discovered before; I boast it is mine.

Even late scholastic philosophy had its *via moderna,* the philosophy of William Ockham and his followers, as well as the *via antiqua* of the earlier 13th-century thinkers.

The period of the Renaissance, in the old sense of the term, was not one of modern progress either politically or socially, morally or materially. In most towns, walls and towers, streets and houses, were little changed even until the 19th century. Houses at Lyons which were listed in 1725 were still identified by the same signs and emblems as in the 11th and 12th centuries. If a new school were started, it would be in some abandoned hospital or half-ruined monastery rather than in a new building. Feudal castles were not dismantled till the 17th century, and the guild system was then essentially the same as it was in the 13th. In the 16th century a good cavalier on a good horse was still as superior a being as there could be in this world. There was no great improvement either in transportation or in sanitation. In fact, Francis Bacon tells us that people bathed less in his time than they used to do. Amid such static external conditions the reading of classical literature and the inspection of Italian or native masterpieces in the fine arts might well rank high. Finally, after making allowance for the introduction of printing, it must be emphasized that in many respects there was a break between the scientific activity of the 14th century and its resumption in the 16th or 17th century.

It is necessary, therefore, to reject Michelet's redefinition of the Renaissance as the discovery of the world and of man, together with all kindred attempts to assess it in vague terms and intangible conceptions such as the medieval mind and the modern mind, or the popular mind and the intelligentsia, individuality and personality, sentiment and spirit. Instead one should return to the original conception of the movement as a revival of classical Latin belles-lettres and the recovery of Greek classical belles-lettres. Since history is continuous, only a loss of records makes an apparent breach in it, but its frontier at any given moment is not a straight line; it has advanced at some points and is backward at others.

The fact that some books on the Renaissance have stretched it backward to include not only Dante and the Goliardic poets but also Ezzelino da Romano and the emperor Frederick II, while others have brought it down to Ariosto and Vesalius or even farther, is enough to show that there can no more be a sharp dividing line between medieval and Renaissance culture than between the Renaissance and the succeeding age.

RENAISSANCE ARCHITECTURE. The Renaissance style of architecture originated in Florence, Italy, during the early 15th century and from there spread throughout most of the Italian peninsula; by the 16th century the new style pervaded almost all of Europe, gradually replacing the Gothic style of the middle ages. The name Renaissance (*rinascimento* in Italian) dates from the period itself, whose goal was the rebirth or recreation of ancient classic culture.

In architecture there was a revival of classic forms and ornament, such as the column and round arch, the tunnel vault and dome; but from this classic vocabulary the Renaissance architects made a completely original architecture.

This article is organized as follows:

I. Introduction
II. Italy
  A. Early Renaissance
  B. High Renaissance
  C. Mannerism
III. France
  A. Early Renaissance
  B. Mannerism
IV. Spain
  A. Plateresque
  B. Classic
  C. Herreran
V. Germany and the Low Countries
VI. England

The periods of European architecture before the Renaissance are discussed in BYZANTINE ARCHITECTURE; ROMANESQUE ARCHITECTURE; and GOTHIC ARCHITECTURE. European architecture after the Renaissance is discussed in BAROQUE AND POST-BAROQUE ARCHITECTURE and MODERN ARCHITECTURE. The classic antecedents of Renaissance architecture are treated in GREEK ARCHITECTURE and ROMAN ARCHITECTURE. *See* also ARCHITECTURE.

I. INTRODUCTION

The Renaissance knowledge of the classic style was derived chiefly from two sources: the ruins of ancient classic buildings, particularly those in Italy, but some in France and Spain; and the treatise *De architectura* by the Roman architect Vitruvius (*q.v.*). At that time it was not realized that Vitruvius' theory was drawn to a great extent from Hellenistic Greek architectural theory, and Renaissance architects were often disturbed by the apparent discrepancies between Vitruvius and the actual Roman ruins.

The Renaissance architects considered the classic orders one of the basic elements of their architecture; the orders were organized on a system of proportions, and proportion was the essence of their theory of beauty. (*See* ORDER.) During the Renaissance five orders were used, the Tuscan, Doric, Ionic, Corinthian and Composite, but various ones were prevalent in the different periods of the Renaissance.

For example, the ornate, decorative quality of the Corinthian order was embraced during the early Renaissance, while the masculine simplicity and strength of the Doric was preferred during the Italian High Renaissance. Following ancient Roman architecture (*e.g.*, the Colosseum or the Theatre of Marcellus) Renaissance architects often superimposed the orders, that is, used a different order for each of the several stories of a building, commencing with the heavier, stronger Tuscan or Doric order below, then rising through the lighter, more decorative Ionic, Corinthian and Composite.

For all the Renaissance arts proportion tended to be the most important predetermining factor of beauty. The great Italian humanist and architect Leon Battista Alberti defined beauty in architecture as "a Harmony of all the Parts in whatsoever Subject it appears, fitted together with such Proportion and Connection, that nothing could be added, diminished or altered, but for the Worse" (*Ten Books on Architecture,* trans. by J. Leoni, book vi, ch. 2, 1755).

The Renaissance architect worked from a fixed unit of proportion, the module, which was usually half the diameter of the column of the order and which determined the size and location of the various parts of his elevation or plan. There was even a relationship between architectural proportions and the leading Renaissance device of perspective (*q.v.*); the Italian painter Piero della Francesca said that perspective represented objects seen from afar "in proportion according to their respective distance." In fact, it was an Italian Renaissance architect, Filippo Brunelleschi, who apparently was the first to formulate perspective. Many Renaissance architects were as concerned with perspective as the painters were, for most Renaissance architecture was meant to be seen from a fixed visual viewpoint, like a painting in perspective, and not from a moving viewpoint as were baroque and modern architecture.

In part because of the interest in proportion, architecture during the Renaissance was raised to the level of a liberal art (or a fine art). During the middle ages it was considered simply a mechanical art and the artists and architects basically craftsmen, their anonymity only occasionally dispelled by the fortunate preservation of building accounts. In the Renaissance the varying systems of proportion were dependent on a knowledge of geometry; architecture became the materialization in space of the principles of geometry and thereby an equal of geometry, which had been a liberal art during the middle ages.

Renaissance architecture was produced no longer by craftsmen but by educated men of some social standing. In Italy during the 15th and 16th centuries the architect gradually acquired this social standing through his knowledge and education which were concerned with the theory and principles of design more than with the craft of building. The Renaissance architect was, therefore, known as an individual. His life and his ideas have been preserved, and he is not merely another name in a building record.

The Renaissance was also the great moment in the history of architecture for the expression of architectural theory. Inspired by the rediscovery or reevaluation of the treatise by Vitruvius, many architects recorded their theories of architecture; some were preserved in manuscript (*e.g.*, those of the architects Francesco di Giorgio and Antonio Filarete), but most were published. Alberti's treatise, *De re aedificatoria,* modeled on Vitruvius, was written in the middle of the 15th century and published in 1485. However, it was during the last three-quarters of the 16th century, the period of Mannerism, that architectural theory flourished. The Italians Serlio, Vignola and Palladio published famous books on architecture at that time. Elsewhere, works were published by the Frenchmen Androuet du Cerceau, Delorme and Jean Bullant; the Fleming Vredeman de Vries; the German Wendel Dietterlin; and John Shute in England.

II. ITALY

Renaissance architecture commenced in Italy about 1420 and flourished until the end of the 16th century, when it was gradually superseded by the baroque style. In Italy there were three principal periods in the development of the Renaissance: (1) the early Renaissance, from the appearance of the new style early in the 15th century to the end of the century; (2) the High Renaissance, approximately the first quarter of the 16th century; and (3) Mannerism, the remaining portion of the 16th century.

The Renaissance began in Italy, where there was always a residue of classic feeling in architecture. A Gothic building such as the Loggia dei Lanzi in Florence continued to use the large round arch instead of the usual Gothic pointed arch, and preserved the simplicity and monumentality of classic architecture. The Renaissance might have been expected to appear first in the city of Rome, where there was the greatest quantity of ancient Roman ruins, but during the 14th and early 15th centuries, when the Italians were impelled to renew classicism, the political situa-

tion at Rome was very unfavourable for artistic endeavour. This was the time of a schism in the church, with the papacy located at Avignon in south France and no central power at Rome. Florence, however, under the leadership of the Medici family, was economically prosperous and politically stable.

A. Early Renaissance

In 1401 a competition was held between sculptors and goldsmiths to design a pair of doors for the old baptistery at Florence. The sculptor Lorenzo Ghiberti won, and a losing goldsmith, Filippo Brunelleschi, resolving to be the leader in one of the arts, then turned to the study of architecture. Brunelleschi spent the period between 1402 and 1418 alternately in Florence and Rome. During this time he studied mathematics intensively and formulated linear perspective, which was to become a basic element of Renaissance art. At the same time Brunelleschi investigated ancient Roman architecture and acquired the knowledge of classic architecture and ornament, which he used as a foundation for Renaissance architecture. His great opportunity came in 1418 with the competition for the completion of the *duomo,* or cathedral, of Florence. The medieval architects had intended a great dome over the crossing of the cathedral, but it had never been created, and no one knew how to accomplish it. Winning the competition, Brunelleschi began the great dome in 1420 (the finishing touches were applied in 1467, after Brunelleschi's death). The Florentine dome is really not in the Renaissance style since it was built with rib construction and a pointed arch form which were medieval. But the dome was raised on a drum, which the medieval architects had not intended; the idea of a dome being made more prominent by the added stature of a drum became characteristic of the Renaissance style. (*See* Dome.)

While he was erecting the dome, Brunelleschi produced in Florence other notable examples of the Renaissance style. The loggia of the Ospedale degli Innocenti (1419–51) was the first building in the Renaissance manner; a very graceful arcade was designed with Composite columns, and windows with classic triangular pediments were regularly spaced above each of the arches. This style was more fully exploited in the church of S. Lorenzo (1419 to *c.* 1470). Using the traditional basilica (*q.v.*) plan (*i.e.,* a long rectangle with the sanctuary at one end), the plan and elevations were organized on a system of proportions with the height of the nave, or central aisle, equal to twice its width. All the ornament is classic with Corinthian columns, pilasters and classic moldings. Brunelleschi used almost exclusively the Corinthian order with the decorative elements cut in a very crisp manner. All the moldings, door and window frames, and orders are of a soft blue-gray stone (*pietra serena*) contrasted against a light stucco wall. The ornamental features have very little projection, being rather lines on a surface. Colour was used in Florentine architecture as a contrast to stress the linear relationships rather than for over-all patternistic use as in north Italian architecture.

The traditional plan for medieval churches was the Latin cross plan, as at S. Lorenzo, with one arm of the cross longer than the others so as to form the nave or main body of the church. During the middle ages this cross plan was considered a symbolic reference to the cross of Christ.

During the Renaissance the ideal church plan tended to be centralized, that is, it was symmetrical about a central point, as is a circle, a square or a Greek cross which has four equal arms. Many Renaissance architects came to believe that the circle was the most perfect geometrical form and, therefore, most appropriate in dedication to a perfect God. Brunelleschi also worked with the central plan. In the Pazzi chapel (1430–42), set down in the medieval cloister of Sta. Croce at Florence, the plan approaches the central type. On the interior it is actually a rectangle, slightly wider than it is deep; at its rear is a square bay for the sanctuary and at the front is a porch. There are three domes, a large one over the centre of the chapel, a small one over the sanctuary and a small one over the centre of the porch on the exterior. Its plan, but not its interior space, resembles a Greek cross. On the exterior the large dome is covered by a conical roof with a lantern at the top. The porch has a horizontal entablature supported by six Corinthian columns but broken in the centre by a semicircular arch which centralizes the composition, repeats the shape of the dome in the porch behind it and gives a lift to the horizontal façade. Above the columns and hiding the tunnel vault over the porch is a lovely paneled wall comparted by coupled Corinthian pilasters. The architecture is very ornate and decorative with medallions of cherub heads on the entablature and a wave pattern (the ancient strigil pattern) on the upper entablature.

Soon after the commencement of the Pazzi chapel, Brunelleschi began a true central plan church, that of Sta. Maria degli Angeli (begun 1434) at Florence, which was never completed. It was very important because it was the first central plan church of the Renaissance, the type of plan which dominates Renaissance thinking. The plan is an octagon on the interior and 16 sided on the exterior with a dome probably intended to cover the centre.

One of the outstanding examples of secular architecture was the Medici palace (1444–59) at Florence by Michelozzo (Michelozzi) di Bartolommeo, a follower of Brunelleschi. Created for Cosimo de' Medici, the great political leader and art patron of Florence, the palace had extensive additions in the 17th century. Arranged around a central court, the traditional Florentine palace plan, the Medici palace (now Medici-Riccardi palace) is a tremendous block on the exterior.

Medieval Florentine palaces were built of great rusticated blocks of stone, as if they had just been hacked out of the quarry, giving the impression of fortification, a desirable effect in that tumultuous time. With the Renaissance some fundamental changes appeared. Michelozzo crowned his palace with a massive horizontal cornice in the classic style and regularized the window and entrance openings. Even the rustication of the stonework was differentiated in each of the three stories. The ground floor has the usual heavy rustication; the second story is marked by drafted stonework with smooth blocks outlined by incised lines; and the third story has smooth ashlar stonework with no indications of the blocks. Unlike medieval patternistic rustication, the rustication of the Renaissance, while carefully distinguished between the stories, set up a logical relationship among them.

This Renaissance treatment of a palace façade was carried further in the Palazzo Rucellai (1447–51) at Florence following the design of the great humanist and architect Leon Battista Alberti. For the first time during the Renaissance Alberti applied classic orders to a palace elevation, using pilasters of the different orders superimposed on the three stories, so that there was another relationship established among the differentiated stories, from the short, strong Tuscan pilaster on the ground floor to the tall, decorative Corinthian at the top. For Alberti the beauty of architecture consisted of a harmonious relationship among the parts, with ornament, including the classic orders, being auxiliary to the proportion.

The culmination of Alberti's style is seen in two churches at Mantua. The earlier, S. Sebastiano (begun 1460, never fully completed), was built on a Greek cross plan and was intended to have in its first design an ancient temple front of six pilasters and a dominating triangular pediment. Even more important was Alberti's other church at Mantua, S. Andrea (begun 1470, completed in the 18th century). Both in plan and interior elevation this church was very influential on later architecture. The plan is a Latin cross, with one long arm for the nave flanked by side chapels, but the crossing at the eastern end was treated almost as if it were of a central plan with the nave added to it. This plan became a favourite for churches of the late 16th and early 17th century. The façade is of square proportion, with a wide bay at the centre twice the width of each of the side bays. The interior elevation was organized on this same alternating system, the so-called "rhythmic bay" which was to be popularized in the early 16th century by the architect Bramante. As a result of this system there is a close correspondence between the interior and exterior composition of S. Andrea.

From Florence the early Renaissance style spread gradually over Italy, becoming prevalent in the second half of the 15th century. In the architecture of north Italy there was a greater interest

in pattern and colour. Colour was emphasized by the use of variegated marble inlays, as in the façade of the Church of the Certosa at Pavia (begun 1491) or in most Venetian architecture. The favourite building material of north Italy was brick with terracotta trim and decoration with which a pattern of light and dark was created over the entire building. On occasions when stone was used, as at the Palazzo Bevilacqua in Bologna (1479–84), the blocks were cut with facets forming a diamond pattern on the façade. This was actually a decorative treatment of rustication. Even the classic orders were affected by this decorative approach. Classic pilasters often had panels of candelabra and arabesque decoration in delicate relief on the surfaces of their shafts; the lower third of a column was often carved with relief sculpture. Florentine artists such as Filarete with his project for the Ospedale Maggiore at Milan (begun 1457) brought to Lombardy in northern Italy classic decoration and a slight knowledge of Renaissance architecture.

From Lombardy the style was transferred to Venice by such Lombard architects as Pietro Lombardo and Mauro Coducci. The church of Sta. Maria dei Miracoli (1481–89) at Venice with its façade of coloured marble revetment is a typical example of Lombardo's work. The Venetian palace, such as the Palazzo Corner-Spinelli (late 15th century) and Palazzo Vendramin-Calergi (1501–09), both of which are by Coducci, with large and numerous windows, was more open than the palaces of central Italy.

At Rome in the second half of the 15th century there were several notable Renaissance palaces, principally derived from the style of Alberti, who spent extensive periods in Rome as a member of the papal court. The Palazzo Venezia (1455–91) has a rather medieval exterior, but set within the palace is a characteristically Renaissance court (1468–71), of which only two sides forming an angle were completed. It has been suggested without definite proof that Alberti may have furnished the design for this court; it at least reveals his influence in its full understanding of the classic style. The court consists of two stories of semicircular arches supported by piers on which are attached superimposed classic half columns, Tuscan below and Ionic above. The model for this arcade is the ancient Colosseum of Rome. The sense of mass created by the heavy piers contrasts with the lighter effect of the early Renaissance court typical of Florence, which has arches supported on columns. The Palazzo della Cancelleria (1485–1511) shows its dependence upon Alberti's style in its façade, which resembles in part his Palazzo Rucellai in Florence. The lower story simply has drafted stonework, but the two upper stories have rather flat Corinthian pilasters as well as the drafted stone. Unlike the Rucellai palace the bays composed by the pilasters alternate wide and narrow, but this alternation had been used by Alberti already in S. Andrea at Mantua. Alberti's influence is also visible in the façades of the churches of S. Agostino (1479–83) and Sta. Maria del Popolo (rebuilt 1472–77) at Rome.

These examples of the early Renaissance in Rome were rapidly approaching the simplicity, monumentality and massiveness of the High Renaissance of the early 16th century. The architect Donato Bramante, who was to create this new style, was active in Lombardy in north Italy, but his work in Milan, as at Sta. Maria presso S. Satiro (about 1480–86), was still completely in the Lombard early Renaissance manner. However, he was in contact at this time with the great Florentine artist Leonardo da Vinci, who was active at the Milanese court. Leonardo was then considering the concept of the central plan church and filling his notebooks with sketches of such plans, which Bramante must have studied. When Bramante moved to Rome at the very end of the 15th century, his study of ancient ruins combined with the ideas of Leonardo and the growing classicism of Roman early Renaissance architecture resulted in the flourishing of the High Renaissance.

B. High Renaissance

High Renaissance architecture first appeared at Rome in the work of Donato Bramante at the beginning of the 16th century. The period was a very brief one, centred almost exclusively in the city of Rome; it ended with the political and religious tensions that shook Europe during the third decade of the century, culminating in the disastrous sack of Rome in 1527 and the siege of Florence in 1529. The High Renaissance was a period of harmony and balance in all the arts, perhaps the most classic moment in this respect since the 5th century B.C. in Greece. It was an idealistic age in which individual characteristics or idiosyncrasies tended to be eliminated. As a result, although the architects are known as individuals, it is sometimes difficult to identify on a stylistic basis the particular architect of a High Renaissance building. The problem of attribution is further complicated by the fact that the style was confined to a small group of architects centring around Bramante in Rome.

Political and cultural leadership shifted from Florence to Rome, particularly because of a group of powerful popes who were interested in developing the papacy as a secular power. The greatest of all was Julius II (1503–13), who was likewise a fabulous patron of the arts. Almost all the leading Florentine and other Italian artists were attracted to Rome. With the exception of Giulio Romano none of the important artists active in Rome at this time were Roman by birth.

Donato Bramante, the leader of this new manner, had already acquired an architectural reputation at Milan. Almost immediately after his arrival in Rome in 1499, there was an amazing change in Bramante's work, as he became the exemplar of the High Renaissance style and lost his Lombard early Renaissance qualities. The Tempietto (1502), or small chapel, next to S. Pietro in Montorio typifies the new style. Erected on the supposed site of the martyrdom of St. Peter, the Tempietto is circular in plan with a colonnade of 16 columns surrounding a small cella. The chapel was meant to stand in the centre of a circular court which was likewise to be surrounded by a colonnade, so that the whole structure was to be self-contained and centralized. The enclosing circular court has never been erected. The ultimate inspiration of the Tempietto was a Roman circular temple, like the temples of Vesta at Rome or Tivoli, but so many notable changes were made that the Renaissance chapel was an original creation. On the exterior it was organized in two stories, the Doric colonnade forming the first story. Above is a semicircular dome raised high on a drum. The present large finial on the dome is of a later date and destroys some of the simplicity of the massing. Niches cut into the wall of the drum help to emphasize the solidity and strength of the whole, as does the heavy Doric order that Bramante was so fond of, in contrast to Brunelleschi who had a predilection for the ornate Corinthian. The monument is very simple, harmonious and comprehensible.

Several churches by other architects present the same qualities as the Tempietto on a larger physical scale. The church of Sta. Maria della Consolazione (1508–34) at Todi by a minor architect, Cola da Caprarola, is likewise centralized in plan, being square with a semicircular or polygonal apse opening off each side. The mass is built up of simple geometric forms, with a cube at the centre surrounded by half cylinders and capped above by the cylinder of a drum and a hemispherical dome. The Florentine architect, Antonio da Sangallo the elder, influenced by Bramante, created his church of S. Biagio at Montepulciano (1518–45) on a Greek cross plan. On the façade in the two recesses of the arms of the cross were to rise two towers, the right one never completed. Otherwise the massing is similar to that of Todi with dome and drum above. All the moldings and ornamental elements were carved with strong projection, so that on the interior heavy Roman arches, with deep coffers containing rosettes, define the tunnel vaults rising over the arms of the church. The sense of solid yet harmonious mass is enhanced by the travertine stone of which it is built.

Sangallo's church at Montepulciano reflects Bramante's greatest undertaking, the rebuilding of St. Peter's at Rome. Early in 1505 Pope Julius II began to consider the question of a tomb for himself appropriate to his idea of the power and nobility of his position. The sculptor Michelangelo soon presented a great project for a freestanding tomb, but such a monument required a proper setting. The Renaissance biographer Vasari claimed that the question of an appropriate location for this projected tomb

brought to the pope's mind the idea of rebuilding St. Peter's, which was in very poor condition. Bramante, therefore, prepared plans for a monumental church late in 1505, and in April 1506 the foundation stone was laid. The projected church was a Greek cross in plan, with towers at the four corners and over the crossing a tremendous dome, inspired by that of the ancient Roman Pantheon but raised in this case on a drum. In elevation there was a very careful definition of all the parts of the church, so that one could visualize the plan from the composition of the elements of the elevation. At his death in 1514 Bramante had completed only the four main piers which were to support the dome, but these piers determined the manner in which later architects attempted the completion of the church.

As important as the central plan churches of this period were several notable secular buildings. At the papal palace of the Vatican next to St. Peter's, Bramante added two important features. The great Belvedere court (begun 1503) was planned to bring together the two disparate elements of the older palace attached to the church and the Belvedere villa of Innocent VIII on the hill above the palace. The new court was terraced up the hillside on three levels joined by monumental stairs. It was enclosed on the two long sides by arcaded loggias with superimposed orders. This large court was completed in the latter 16th century with some minor changes, and in 1587 the whole concept was destroyed by the building of the present Vatican library across the centre of the court. Just before his death Bramante also began a series of superimposed loggias attached to the face of the old Vatican palace looking out over the city and river. Completed by Raphael, there are two superimposed arcades with Tuscan and Ionic orders and a colonnade with Composite columns.

The largest palace of the High Renaissance is the Farnese palace (*c.* 1517–66) at Rome designed and commenced by a follower of Bramante, Antonio da Sangallo the younger, nephew of the older Sangallo. At Sangallo's death in 1546 Michelangelo carried the palace toward completion, making important changes in the third story. On the exterior Sangallo gave up the use of the classic orders as a means of comparting the façade into a number of equal bays; he used instead a façade more like the Florentine, but with quoins or rough cut blocks of stone at the edges of the elevation to confine the composition in a High Renaissance fashion. The façade is composed in proportions as a double square. On the interior the central square court is more classic using superimposed orders. Based on the ancient Roman Theatre of Marcellus or the Colosseum, the two first floors have an arcade supported by rectangular piers against which are set half columns. On the third story Michelangelo eliminated the arcade and used pilasters flanked by half pilasters which destroyed the High Renaissance idea of the careful separation and definition of parts.

One of the most charming buildings of the period is the Villa Farnesina (1509–21) at Rome by Bramante's finest pupil, Baldassare Peruzzi, who came from Siena. Designed for the fabulously wealthy Sienese banker Agostino Chigi, the villa was the scene of numerous fantastic banquets. A suburban villa, the Farnesina was planned in relation to the gardens around it with two small wings projecting from the central block toward the gardens. Originally there were two open loggias facing the gardens from two sides of the villa; one loggia is now completely walled in. The elevation appears as two stories comparted into equal bays by Tuscan pilasters. Other important buildings were designed by the painter Raphael, such as the Villa Madama (begun 1517) at Rome or the Palazzo Pandolfini (1516–20) at Florence.

C. Mannerism

From the third decade of the 16th century political and religious tensions erupted violently in Italy, particularly in Rome, which was sacked in 1527 by imperial troops. The school of Bramante and Raphael, which had produced the High Renaissance style, was dispersed throughout Italy as the artists fled from devastated Rome. Two years later another imperial army, with the backing of the Medici, besieged the city of Florence, imposing upon Michelangelo the difficult choice of supporting his native city or the family which had protected and patronized him. The Medici were soon established in Florence not merely as a leading family but as the outright rulers. In such a period of insecurity, the harmonious and self-sufficient manner of the High Renaissance could not survive. It was gradually replaced by a complex style, sometimes called Mannerism, which continued until the end of the 16th century when the baroque style developed. Mannerism was antithetical to most of the principles of the High Renaissance. In place of harmony, clarity and repose it was characterized by tension, complexity and novelty. Mannerist architects were no less interested in ancient classic architecture than their predecessors; in fact, they displayed an even greater knowledge of antiquity. However they found other qualities in Roman architecture to exploit.

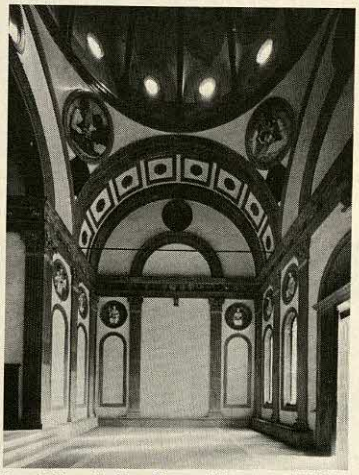
The change in style can be seen in the work of an architect, Baldassare Peruzzi, who was active in both periods. Unlike his High Renaissance Villa Farnesina, Peruzzi's design for the Palazzo Massimo alle Colonne (about 1535) in Rome shows indications of Mannerism. The façade of the palace was curved to fit the site on which it was erected; instead of remaining the passive form it had been in the earlier phases of Renaissance architecture, the wall surface was beginning to assert itself. The classic order is limited to the ground floor of the palace; the upper three stories have imitation drafted stonework made of brick covered with stucco, inscribed to feign stone coursing. Under these three stories in the centre of the façade is a loggia or colonnade, which seems of questionable adequacy as a support for the apparent load. The second story has classic rectangular windows crowned by Peruzzi's usual neat lintel supported on volutes, but the windows of the upper two stories are set horizontally with rather elaborate curvilinear moldings about them. There is, therefore, no longer a harmonious balance between the various stories. The architecture shows a greater emphasis on decorative qualities than on the expression of structural relationships.

In its earlier phase, until about 1550, Mannerism presented a strong reaction against the High Renaissance. In the latter half of the century the free treatment of the classic vocabulary which was typical of early Mannerism became somewhat restrained. In central Italy, because of the impact of the sack of Rome, the quantity of early Mannerist architecture was limited. A typical example is the project which Antonio da Sangallo the younger prepared for the completion of St. Peter's at Rome. A wooden model (begun 1539), still preserved in St. Peter's, reveals that Sangallo's plan is a combination of a central plan church with a large vestibule which makes the whole scheme approach a Latin cross. As a result, the exterior of the church resembles a Latin cross, but the interior space denies this by being centralized. In the same way the exterior elevation, unlike Bramante's project, does not express clearly the disposition of the interior of the church. The number of the architectural elements is increased so that the simplicity and clarity of the High Renaissance is lost. The dome of Sangallo's project has two superimposed arcades around its base and a double lantern above, so that the dome form is almost completely lost in a many-tiered, wedding-cake effect.

One of the great figures of the Mannerist period was the Florentine artist Michelangelo. He executed some extreme examples of Mannerist architecture at Florence. In his Laurentian library (1523–71) the vestibule fully illustrates his manner. Spatially it is a tall box set on end rising three stories. The large columns that line the wall of the main story are set into recesses so that a question arises as to whether the column or the wall is the supporting element. This treatment enlivens the expressive quality of the wall, for unlike its rather passive expression in the High Renaissance the wall now seems to be pressing forward between the columns. The small decorative pilasters were designed to taper toward the base in contrast to the usual classic and Renaissance pilaster. The small floor area of the vestibule is almost completely filled with the staircase leading up to the reading room. The stairs are an extreme example of the freedom of Mannerism; the function of the stairs is subordinate to their design. Commencing as three flights of stairs, the side flights at the top divert their traffic into the middle one, which was designed with curved steps so that the total effect resembles moving lava. The stair-

Rear of St. Peter's, Rome. Rebuilding began in 1506 from plans by Donato Bramante; architects who assisted in its construction included Michelangelo, Giacomo della Porta, and Carlo Maderno

Church of S. Lorenzo, Florence; *c.* 1419–*c.* 1470. Architect, Brunelleschi. The nave and aisles of this Latin-cross basilica are separated by Corinthian columns



Pazzi Chapel, Sta. Croce, Florence; 1430–42. Architect, Brunelleschi

The Tempietto, or small chapel, in courtyard of S. Pietro in Montorio, Rome; 1502. Architect, Donato Bramante

S. Andrea, Mantua, Italy, begun 1470 and completed in the 18th century, built on a Latin cross plan. Architect, Leon Battista Alberti

Palazzo Corner-Spinelli, Venice; late 15th century. Architect, Mauro Coducci. The façade has large, symmetrically arranged windows

way dominates the vestibule instead of remaining a neutral, functional form. The whole atmosphere of the vestibule is that of an architectural space in tension, which contrasts with the quiet monotony of the long horizontal reading room above.

Michelangelo's later architecture in Rome was more restrained but still reveals some of the qualities of Mannerism. At the death of Sangallo in 1546 Michelangelo was commissioned to complete the great church of St. Peter's at Rome. During the next 18 years he was able to complete most of his design for the church, except the façade and great dome above. In plan he returned to a central plan church reminiscent of Bramante's idea but with fewer parts. His elevation, still visible at the rear or sides of the church, is composed of gigantic pilasters with a rather high attic story. Between the pilasters are several stories of windows or niches. Unlike the harmonious orders and openings of the High Renaissance, these are constricted by the pilasters so that a tension is created in the wall surface. Michelangelo planned a tremendous semicircular dome on a drum as the climax of the composition. Engravings of his original project suggest that this dome would have been overwhelming in relation to the rest of the design if the church had been completed in accordance with his concept. The great central dome was executed toward the end of the 16th century by Michelangelo's follower Giacomo della Porta who gave a more vertical expression to the dome by raising it about 25 ft. higher than a semicircle. This resulted in a slightly pointed profile which became the prototype for the baroque dome, whereas the semicircular dome had been typical of the Renaissance. In the early 17th century Carlo Maderno added a large nave and façade to the front of the church, converting it into a Latin cross plan and destroying the dominating quality of the dome, at least from the exterior front.

Early Mannerism in north Italy developed out of the dissolution of the school of Bramante after the death of Raphael in 1520 and the sack of Rome in 1527. Giulio Romano, the chief assistant of Raphael, became court artist and architect in the city of Mantua, while Michele Sanmicheli, a pupil of Bramante and Antonio da Sangallo the younger, returned to practise in his native town of Verona and at nearby Venice. Romano's Palazzo del Te at Mantua has a formal exterior with imitation drafted stonework and Doric pilasters, but the pilasters were not spaced in the High Renaissance manner, with an absolute regularity or an alternate rhythm of wide and narrow bays. The pilaster bays instead have a much more complex rhythm of several different widths. Mannerist tension was expressed in the court by the designing of every third triglyph of the Doric frieze to drop slightly, deliberately giving a sense of insecurity that tended to deny the structural expression of the order.

The leading early Mannerist architect in Venice was the Florentine sculptor Jacopo Sansovino, who fled to the north from Rome after the sack. Sansovino's architecture, as represented by the loggetta (1537–40) at the foot of St. Mark's campanile or by the Library of St. Mark's (Libreria Vecchia; 1536–88), is an example of the very decorative side of Mannerism. The library has two stories of arcades; the upper story is much taller than the lower. It has no basement, merely three low steps, so as to match the Gothic Palazzo Ducale opposite it. The upper entablature is extremely heavy, equaling half the height of the Ionic columns on which it rests. The decorative nature of the building is indicated by the fact that relief sculpture has been applied universally to the entablature and spandrels of the arches, with no unadorned wall surfaces.

This period of free and decorative Mannerism was followed by the more restrained, classic phase of late Mannerism seen to perfection in the architecture of one of the greatest architects of the Renaissance, Andrea Palladio. His native city, Vicenza, on the mainland not far from Venice, was almost completely rebuilt with edifices after his design; the Venetian mainland around Vicenza was profuse with his villas. The Villa Capra or Rotonda (1550–53; with later changes) near Vicenza is magnificent in its simplicity and massing. In the centre of a cubelike block (a cube is typical of most Palladian villas) is a circular hall, and on all four sides are projecting classic temple fronts as porticoes. There is an absolute classic rigidity in the plan which when applied to domestic architecture is even more abstract than High Renaissance architecture. In Venice Palladio built several churches, all with the Latin cross plan and rather similar façades. S. Giorgio Maggiore (1566–1610) has a Roman temple front, on four giant half columns, applied to the centre of the façade; abutting the sides are two half temple fronts with smaller coupled pilasters. The resulting composition suggests the interpenetration of two complete temple fronts in a Mannerist way, since the elements of the composition are less independent than they would be in High Renaissance architecture, although the details are fully classic. Also typical of Mannerism is the way in which the interior space, instead of being classically confined, is permitted to escape through a colonnaded screen behind the sanctuary into a large choir at the rear.

Palladio's greatest fame in the history of architecture rests on his treatise, *I Quattro libri dell'architettura* (1570). The book promulgates a very classic theory of architecture; in fact, one chapter (I, xx) on the abuses in architecture decries some of the characteristics of Mannerism. In the 17th century Palladio's writings played an important role in the formulation of the French Academic theory of architecture.

In England there were at least two waves of Palladianism (*q.v.*), one centred around Inigo Jones in the early 17th century and another around Lord Burlington in the 18th century, which later spread to America.

Late Mannerism at Rome and Florence was more varied. Pirro Ligorio's Casino of Pius IV (1558–63) at the Vatican is extremely decorative, with its façade covered with rich stucco relief and pebble mosaic ornament. In Florence the Uffizi palace (1560–74) by Giorgio Vasari and others was built about a very long, narrow court that seems to have been created by the compression of the tall side walls. It has a more dynamic spatial expression than the harmonious passive courts of the High Renaissance, which are generally square or circular. The most important architect of this period is Giacomo da Vignola, who wrote a treatise, *Regole delli cinque ordini d'architettura* (1562), devoted solely to a consideration of the architectural orders and their proportions. Like Palladio's book, Vignola's *Rules* became a textbook for later classic architecture. Of his many buildings the project for the church of Gesù (1568–75) at Rome, the central church of the Jesuit order, was very influential on the later history of architecture. The plan is a Latin cross with side chapels flanking the nave, but the eastern end is a central plan, capped by a dome. The plan was derived from Alberti's early Renaissance plan of S. Andrea at Mantua. The Gesù plan was imitated throughout Europe, but especially in Italy, during the early baroque period of the 17th century. Vignola built the church except for its façade, which was executed by Giacomo della Porta. Della Porta, inspired by Vignola's original design, created a façade concentrated toward its centre, which, like the plan, was the prototype for most early baroque façades of the late 16th and early 17th century.

III. FRANCE

The Renaissance style of architecture appeared in France at the very end of the 15th century and flourished until the end of the 16th century. As in other north European countries and Spain the new Renaissance manner did not completely oust the older Gothic style, which survived in many parts of France throughout the 16th century. French Renaissance architecture is divided into two periods: the early Renaissance, from the end of the 15th century until about 1530, and Mannerism, from about 1530 to the end of the 16th century.

A. Early Renaissance

The many invasions of Italy from 1494 until 1525 by French armies acquainted the French kings and nobles with the charms of Renaissance art. During the reigns of Louis XII and Francis I the French possessed the city of Milan for the first 25 years of the 16th century. It was in Lombardy, therefore, that contact was made between French art and the Renaissance, and it was the

Lombard Renaissance style that appeared in France during the early Renaissance.

The new style had a certain prestige since it was imported by the nobility and aristocracy, while the middle class burghers continued to support their native Gothic style. This social difference also applied to the artists themselves. The French aristocracy imported Italian architects and artists who had been influenced by the Italian Renaissance, in which artists were considered to have a higher social level than artisans. The French builders and craftsmen who executed the designs of the Italians still belonged to the social level of medieval artisans. This created a friction between the two groups, which was, of course, furthered by the French resentment toward imported foreign artists.

With the exception of a few brief outcroppings of classicism in such centres as Marseilles and Gaillon, French early Renaissance architecture was centred in the Loire valley, since the capital of France was at Tours during the reign of Louis XII and the early part of the reign of Francis I. Most of the new architecture was secular, such as the château (*q.v.*), which was descended from the medieval feudal castle, combined with the idea of an Italian villa. A characteristic example is the château at Blois, where two wings in the early Renaissance manner replaced parts of the 13th-century château. The first wing, erected for Louis XII (1498–1503), is almost completely in the Flamboyant style (*q.v.*) and structure, with high roofs, an asymmetrical elevation, depressed arches and ogee arches. The only hint of the Renaissance is the occasional use of a bit of classic decoration, such as the egg and dart molding, mingled with the Gothic. The second wing, built by Francis I (1515–24), is more nearly in the Renaissance style. The structure remained Gothic with a high roof and dormers and the irregular spacing of the vertical windows, but all the ornament was in the classic mode, although its handling was often nonclassic. Classic pilasters were used to divide the elevation into bays, but there is no consistency in the proportions of the pilasters. The most notable feature of the interior elevation of the wing of Francis I is a great octagonal open staircase, five sides of which project into the court. Within is a spiral staircase set on a continuous tunnel vault that is supported by radiating piers. On the surface of the piers are panels in low relief of arabesque decoration, of a type which is found often in Lombard Renaissance architecture. The richness of the Lombard style blends very well with Flamboyant Gothic, which had always been characterized by intricate and rich decoration. The exterior elevation of the wing of Francis I consists of a series of open loggias, the two lower ones arched, the upper one with a straight entablature, reminiscent of the famous series of loggias that had just been completed by Bramante and Raphael at the Vatican palace in Rome. However, the Italian High Renaissance concept was expressed in France in early Renaissance terms with squat pilasters, irregularly spaced bays and somewhat depressed arches.

The finest example of the early Renaissance style is the château or hunting lodge erected for Francis I at Chambord (1519–47). The Italian architect Bernabei Domenico da Cortona presumably made the basic model for the château, but the designs of Italian architects were usually executed by French builders, in this case Pierre Nepveu, often with many changes. Chambord is a tremendous structure, about 500 ft. wide, with a plan showing the gradual breakdown of the old castle plan. There is a rectangular court surrounded by walls with round towers at the corners, but on three sides of the court there are only low curtain walls. The old donjon developed into the château proper as a blocklike building with round towers at each corner. The flat passageways over the curtain walls and on top of the central block were intended to form galleries from which the ladies of the court could observe the hunt. The plan of the main block of the château reveals Italian influence in its symmetrical organization on cross-axes with a double spiral staircase at the centre. In the four corners left by the cross-axes are four identical apartments, each of which consists of three basic rooms (chamber, antechamber and cabinet); this form of apartment was from this time the favourite unit of French domestic planning. Typically for this period, the silhouette and structure remained Gothic in elevation, with strip windows, a multiplicity of elements and a general vertical expression. However all the ornament is in the classic vocabulary of pilasters, round arches, and at times a geometric decoration of slate panels set in the cream-coloured stone.

B. Mannerism

Commencing about 1530 Francis I imported numerous Italian artists, such as Il Rosso, Primaticcio, Serlio, Vignola and Cellini. Most of these artists were Mannerist in style, followers of Michelangelo or Raphael, so that the new period of French architecture partook of Italian Mannerism. The relations between the French and Italian artists became more strained, in part as a result of factions in the royal patronage. Francis I and his Italian daughter-in-law Catherine de Médicis favoured the imported Italians, while the son and successor of Francis I, Henry II, and the latter's mistress Diane de Poitiers supported the French artists. The style that resulted from this tension lasted until about 1590 and is sometimes known as the style of Henry II, although it actually was produced under five different kings, beginning late in the reign of Francis I.

The full influence of the new Italian style can best be seen in the château at Fontainebleau. In 1528 Francis I began to make revisions and additions to his medieval château, the exterior architecture being carried out by French builders under Gilles Le Breton, and, therefore, belonging to the French early Renaissance manner. The Italian mannerist painter, Il Rosso, after his arrival in 1530, was placed in charge of the interior decoration of the Gallery of Francis I (1535–37). The gallery is a long, narrow room covered by a wooden ceiling with rather intricate coffering. On each side of the room is a high dado of carved walnut with rich decoration above of stucco relief sculpture and painting. As Rosso was a Mannerist painter it meant that France went directly from the early Renaissance style of the Loire châteaux to Mannerism. This was natural for the French since Mannerism has affinities with the early Renaissance and late Gothic styles; it appealed to the French whose traditional native style was Gothic. Rosso, who died in 1540, was succeeded by another Italian, Primaticcio, who decorated the ballroom or gallery of Henry II (1548–56) and added the wing called the Aile de la Belle Cheminée (1568) at Fontainebleau.

The most important Italian architect to build in France was Sebastiano Serlio, a pupil of Baldassare Peruzzi, who arrived in 1541 to take Rosso's place as court architect. Serlio prepared plans for the rebuilding of the royal palace of the Louvre at Paris, but his ideas seem to have been too grandiose for Francis I. He did manage to build two châteaux, the casino of the Cardinal of Ferrara at Fontainebleau (about 1546), now destroyed, and the château of Ancy-le-Franc (about 1545–55) in Burgundy. Encountering opposition to his architecture from the French builders, Serlio devoted most of his time to an architectural treatise which he had begun in Italy. Various books of the treatise were published during his lifetime from 1537 on, but the collected work was published after his death with the title *Tutte l'opere d'architettura et prospetiva* (1584). This treatise was quite influential in spreading the Renaissance style in France, England, and the Low Countries.

The influx of Italian artists soon compelled the French architects to adopt Renaissance principles of design as well as Renaissance ornamental details. No longer content to be builders following the guild tradition, many of the French architects began to study the theory of design and often went to Italy as the source of the Renaissance style. A typical example was Jacques Androuet du Cerceau the elder, who was in Rome probably in the 1540s and was more important for his writings on architecture than for executed building. In addition to several treatises on architecture, Androuet du Cerceau published *Les plus excellents bastiments de France* (1576–79), two volumes of engravings of the most notable buildings in France in the Renaissance manner. As many of the buildings have been destroyed or changed, his book is an indispensable source for a knowledge of the architecture.

After Serlio's failure with the palace of the Louvre in Paris, a French gentleman of the court, Pierre Lescot, was ordered to

design and build a Renaissance palace to replace the medieval castle of the Louvre. During the latter part of his reign Francis I centred the capital of France at Paris rather than in the Loire valley. Lescot in collaboration with the famous sculptor Jean Goujon designed a palace in 1546 set around a square court about 175 ft. wide. Only two sides, the west and south, of Lescot's court were built (1546–51). The execution and amplification of this design extended to the middle of the 19th century. The small section carried out under Lescot, the gallery of Francis I, reveals a thorough understanding of the principles of Italian design, but is expressed in French terms. The classic elements are used as low-relief surface decoration with little emphasis on mass.

The two leading architects of the second half of the 16th century, Philibert Delorme and Jean Bullant, studied in Rome. Delorme was trained as a builder before going to Rome and, therefore, was always interested in the constructive side of architecture as well as in the theory of design. About 1546 Delorme was commissioned by Henry II's mistress, Diane de Poitiers, to design her château at Anet. The original château (about 1546–52) formed three sides of a court closed at the front by a screen wall and entrance gateway. Much of the château has been destroyed; only the left wing of the house, the screen wall and the chapel which formed part of the right wing survive. The entrance gateway, which originally contained Cellini's "Nymph of Fontainebleau" (now in the Louvre), is very Mannerist with a complicated superstructure, a semicircular arch with raised bands cutting across the moldings, and, at the top, a bronze group of a stag which strikes the hour with his hoof as the accompanying hounds bay mechanically. The chapel at Anet has a centralized Greek cross plan with a large circle capped by a dome at the crossing. The exterior of the chapel is Mannerist with the windows cutting through the entablature and half pediments abutting the main block.

Delorme commenced in 1564 a large palace called the Tuileries, since it was situated on the site of tileworks in front of the Louvre. It was originally conceived as a very large building, but the architect was able to carry out only a very small section, which was destroyed in 1871.

Again elements of Mannerism were visible. On the first story Delorme used his own so-called French order, consisting of Ionic half columns and pilasters with decorative bands across the shafts, but this order was actually an Italian Mannerist treatment of the classic order. Delorme also wrote on architecture. His most important publication, the *Premier tome d'architecture* (1567), was based on Vitruvius and Alberti, but it is much more practical in its approach than Alberti's work, since it was largely drawn from Delorme's own practice.

Jean Bullant also wrote a book on architecture, *Reigle généralle d'architecture des cinq manières de colonnes* (1564), inspired by the Italian Vignola's treatise which was issued two years previously. In fact, Bullant's architecture was rather like that of Vignola in that it was very classic in details but often Mannerist in relationships. His early and best preserved works were for Anne, duc de Montmorency and constable of France: part of the château of Ecouen (about 1555) and the chatelet (about 1560) at the château of Chantilly. The last shows many Mannerist qualities. For example, the main block of the chatelet is two stories high, but it is comparted by a series of pilasters that are higher than one story, yet not as high as the two stories. This is typical of Bullant's work; it results in the upper windows cutting through the cornice and ending as dormers in the roof. He was also very fond of penetrating the lower part of his window pediments, either with the arch of the window or with a separate little window.

The architecture of the second half of the 16th century was typically Mannerist; numerous architectural treatises appeared, as they had in Mannerist Italy. The Mannerist style died out in the early 17th century as slight hints of the baroque style blended with a renewed Classicism to form gradually the Academic style prevalent in the 17th century.

IV. SPAIN

The unification of Spain in 1492, with the final expulsion of the Moors, was accompanied by the appearance of Italian Renaissance decorative elements in Spanish architecture. There were three phases of Spanish Renaissance architecture: (1) the early Renaissance or Plateresque, from the late 15th century until about 1560; (2) a brief classic period, coexistent with the Plateresque from about 1525 to 1560; and (3) the Herreran style from 1560 until the end of the 16th century.

A. Plateresque

The earliest phase of Renaissance architecture in Spain is usually called the Plateresque (*q.v.*) (from *platero*, "silversmith") because its rich ornament resembles silversmith's work. There has always been a long tradition in Spain of elaborate decoration, explained in part as an influence from Moorish art. The Moors, of course, possessed almost all of Spain during the middle ages and left this decorative heritage to the Spaniards. During the early 16th century minor north Italian sculptors and artisans, particularly from Lombardy and Genoa, were imported into Spain to execute tombs and altars for the Spanish nobles and ecclesiastics. These artisans introduced the north Italian Renaissance vocabulary of classic decoration, such as the pilaster paneled with arabesque or rinceau strips or the candelabrum shaft. Spanish architects picked up these elements and applied them to their buildings.

The Renaissance Plateresque style is purely one of architectural ornament. There was no change in structure; heavy walls were used with either Gothic ribbed vaults or intricately carved wooden ceilings, indicating Moorish influence. Many of the elements of decoration also preserved the influence of Gothic and Moorish art, such as the Flamboyant Gothic pinnacle and pierced balustrade, or coats of arms and bits of heraldry used as ornamental motifs. Richly coloured tiles created decorative patterns on the walls as in Moorish art. The richness of the classic decoration imported from north Italy blended effectively with the elements of the Moorish and Flamboyant Gothic styles to form the new Plateresque style. The luxuriance of its ornament was a fitting expression of the splendour-loving culture that Spain developed as the wealth of the Americas began to pour in during the early 16th century.

In most cases the new Plateresque decoration was confined to rich spots or panels of ornament around the portals and windows of the buildings. These ornamental areas were relieved by large expanses of bare wall, as in the façade of the Royal hospital at Santiago de Compostela (begun 1501) by Enrique de Egas, or his Hospital of Santa Cruz at Toledo (1504–14).

The greatest centre of the Plateresque style was the town of Salamanca, with buildings such as the university (about 1516–29) and the Monterey palace (1539). Perhaps the most outstanding example of the style is the Ayuntamiento, or town hall, of Seville (1534–72) by Diego de Riaño, with Lombard paneled pilasters on the ground floor and half columns completely covered with relief sculpture on the second floor. Also in the Lombard manner are the numerous medallions spotted over the wall under the windows or between the pilasters.

B. Classic

Although the exuberant Plateresque style lingered in some regions until about 1560, it was soon superseded by a much more classic style, which appeared in 1526 in the palace of Charles V within the Alhambra (*q.v.*) at Granada. The palace of Charles V was the first Italian classical building in Spain, in contrast to Plateresque buildings whose classicism was limited to a few elements of Italian Renaissance decoration. Charles V as king of Spain and the Holy Roman emperor was the most powerful political figure in Europe. It was his army that invaded Italy and sacked the city of Rome in 1527 as Pope Clement VII cowered in the Castel San Angelo. As a result of his political and military power, his wealth (which was enhanced by the gold of Mexico and Peru) and his adroit diplomacy, Charles V dominated Italy, as well as Spain, the Low Countries and Austria. His palace in the Alhambra reflected the increasing contact with Italy. Designed by the Spaniard Pedro de Machuca, who had studied in Italy, the work on the palace of Charles V continued through most of the 16th century, but it has never been completed.

The palace is square in plan with a huge central circular court (100 ft. in diameter), which was intended for bullfights and tournaments. The plan is, therefore, fully Renaissance, being centralized and symmetrical; it is organized on cross-axes formed by the four entrances, one in the centre of each side. The façade shows a full understanding of the principles of Italian Renaissance design in its superimposition of orders (*i.e.*, Ionic pilasters or half columns above Tuscan, and Corinthian above Ionic), and in the alternating rhythm of the triangular and segmental pediments above the windows of the second story. The interior court is surrounded by a colonnade with a similar superimposition of Doric and Ionic.

C. Herreran

The classicism of the palace of Charles V was succeeded by an extremely austere and cold style named after the greatest Spanish architect of the 16th century, Juan de Herrera. Perhaps more important than the architect was the social and cultural atmosphere in which the Herreran style developed, from about 1560 to the end of the 16th century. Charles V had been a true Renaissance prince; his only son Philip II, who came to the throne in 1556, was one of the most typical representatives of the age of Mannerism as it was manifested in Spain. Philip II was morbid and melancholic, a religious fanatic, against whose strict rule the Low Countries soon rose in revolt, beginning the difficulties that gradually dispelled Spanish political and cultural power in Europe.

The finest example of the Herreran style illustrates clearly the change in cultural atmosphere under Philip II. This is the palace-monastery of the Escorial (*q.v.*) (1563–84), which Philip II had built as a retreat on a rather dreary plain outside Madrid. It is a great contrast to the worldly palace of Charles V with its tournament court set in the luxurious, sensuous Alhambra. The Escorial was more than a royal palace, as it also contained provisions for a monastery and college within its great complex. A city in itself, the Escorial was planned as a tremendous rectangle (675 ft. by 525 ft.), with a large church at the centre dominating the whole. The orientation toward religion is indicative of the age of the growing Counter-Reformation, which was in part opposed to the secularism of the classic Italian Renaissance.

The Escorial was begun by the architect Juan Bautista de Toledo, who may be responsible for the planning, but the execution and architectural style was that of his assistant and successor, Herrera. Philip II himself reviewed the drawings for the palace, removing anything ornamental or ostentatious. On the exterior the architecture is very simple, a plain wall with a monotonous series of unadorned windows expressing the general monastic character of the whole. The only element of the classic Renaissance on the exterior is at the central portal with two stories of giant Doric half columns supporting a classic triangular pediment. The church, at the centre of the complex, has two bell towers and a great dome set on a drum, which surmount the whole. The austerity is enhanced by the cold, gray granite of which the Escorial was built. On the interior a similar severity of manner is indicated by the lack of decoration. Except for the classic Doric order, which is the least ornamental of the orders, there is no architectural decoration. Plain arches of stone were used under the vaults without any coffering. Occasional raised panels on the wall surface suggest where Plateresque ornament would be located normally, but instead of relief sculpture, there are only starkly smooth panels. Even the Doric order was handled severely; the pilasters on the interior show no entasis (*i.e.*, an upward taper of the width of the pilaster to give a sense of lightness and to relieve the strict verticals). The Escorial is impressive in its size and mass and in the consistency of its austerity, but it has a forbidding quality that no other building can match. Other examples of Herrera's design are the cathedral at Valladolid (begun 1585, completed in the 18th century) and the court of the Lonja, or Exchange, of Seville (1583–98).

V. GERMANY AND THE LOW COUNTRIES

The burgeoning of Italian Renaissance architectural forms in Germany was even slower than in other north European countries. Only by the middle of the 16th century was the Renaissance style manifestly important, generally in those regions in closest contact with Italy, such as southern Germany or the trade route along the Rhine river leading from the south to the Low Countries. The style lingered in Germany until about the middle of the 17th century. The few hints of classicism in Germany prior to the mid-16th century can be considered the early Renaissance phase. They were limited to minor architectural monuments, such as the Fugger chapel in St. Anna at Augsburg (1509–18), which was the first Renaissance building in Germany, or they consisted of bits of Renaissance decoration attached to Gothic structures. An example of the latter is the Schloss Hartenfels at Torgau (1532–44) by Konrad Krebs, which is completely medieval in structure but has occasional fragments of classic ornament, arabesque pilaster strips, candelabra and medallions applied to the surface. A great staircase in the court was somehow derived from that of the French château at Blois, indicating that the Renaissance influence was fourth hand, passing from its source in central Italy through Lombardy, and then to France and eastern Germany.

After 1550 Renaissance-style architecture in Germany often had Mannerist details derived from Italian ornamental engravings. German architecture of this period was abundant with medallions, herms (*i.e.*, architectural elements topped by human busts) and caryatids and atlantes (*i.e.*, human figures used as columns or pilasters). The German treatise on the five orders by Wendel Dietterlin entitled *Architectura* (1593) is profuse with Mannerist ornament. An architectural example is the Otto Heinrichsbau (1556–59) added to the Gothic castle at Heidelberg (burned by the French in 1689). The three tall stories presented the usual verticality of northern architecture, but there was an understanding of the classic superimposition of the orders with Corinthian above Ionic. However, there was a certain freedom in the treatment of the orders, for a Doric frieze was supported by the Ionic pilasters.

From Italian Mannerism came the rustication of the lower order, the use of herms as window mullions and the caryatids flanking the portal. Other examples of the German Renaissance are the porch of the Rathaus, or town hall, at Cologne (1569–73) by the Dutchman Wilhelm Vernuiken and the Friedrichsbau (1601–07) added to the castle at Heidelberg by Johannes Schoch.

In the Low Countries, Flanders, because of trade and finance, was in close communication with Italy from the 15th century. As a result there are slight hints of the Renaissance style in the architecture of the early 16th century, as in the palace of Marguerite of Austria, now the Palais de Justice (1507–25), at Malines completed by Rombout Keldermans.

The most important building of the Flemish Renaissance style was the Stadhuis, or town hall, at Antwerp (1561–65), designed by Loys du Foys and Nicolo Scarini and executed by Cornelis de Vriendt (Floris). It was decided to replace Antwerp's small medieval town hall with a large structure, 300 ft. long, in the new style, as a reflection of its prosperity as the leading northern port of the 16th century. As with many northern buildings there is a lack of monumentality, for its physical hugeness is not expressed in the way that it would be in an Italian building. There is a low basement with a rusticated arcade, originally used by traders during fairs. Above are two principal stories with superimposition of Doric and Ionic pilasters, between which large windows almost completely open each bay.

The advent of the baroque style early in the 17th century replaced the Renaissance in Flanders much sooner than it did in Germany. There were a few examples of the 16th century Renaissance style in the northern Low Countries, such as the town hall at Leyden (1579) and the town hall of The Hague (1565). It was during the 17th century, when Holland was independent of Spain, that architecture flourished.

VI. ENGLAND

The Renaissance style of architecture made a very timid appearance in England during the first half of the 16th century, and it was only from about 1550 that it became a positive style with local qualities. In fact, the Gothic style continued in many parts

of England throughout most of the 16th century, and English Renaissance architecture was a very original fusion of the Tudor Gothic (*see* TUDOR PERIOD) and classic styles. This style flourished until the early 17th century when the architect Inigo Jones created a much more Italianate style that replaced the English Renaissance style.

During the reign of Henry VIII (1509–47) some elements of Italian Renaissance decoration were imported by England through a few minor Italian artists, such as Pietro Torrigiano who executed the tomb of Henry VII (1512–18) in Westminster abbey. At the great palace of Hampton Court, begun by Cardinal Wolsey in 1514 and continued by Henry VIII until 1540, a few bits of Italian Renaissance decoration have been added, although the structure is completely in the Tudor manner. On the gateways are several terra-cotta medallions by the Italian Giovanni da Maiano, and there is a symmetry and regularity in the plan of the palace that hints of the Renaissance. (*See* also ELIZABETHAN STYLE.)

The Renaissance style really begins in England in the middle of the 16th century in architecture built for the circle of the Lord Protector Somerset, who served as regent after Henry VIII's death. During the 16th century the patron played a much greater role in the development of English Renaissance architecture than did the architect; there were almost no professional architects who were trained as the Italians were in the theory of design and building. Most of the building was executed by mason- or carpenter-designers. A typical example of the role of the patron in introducing the Renaissance style to England is to be found in the quadrangle which John Caius added to Gonville college, now Gonville and Caius, at Cambridge (*q.v.*). Caius had spent a long time in Italy as well as elsewhere in Europe. The architecture of the new court was basically Tudor Gothic, but Caius planned three gateways in connection with the court, two of which were in the Italian style. The three gates were to mark the progress of the student through the university. At the entrance was the Gate of Humility, an unadorned doorway, now destroyed. The Gate of Virtue, opening into the new quadrangle, is a fine classic portal with Ionic pilasters, but with a Tudor Gothic many-centred arch for the opening. Finally the Gate of Honour is a separate tiny triumphal arch leading out toward the schools for the final disputation and degree. Caius probably designed these gates with the aid of the Flemish architect Theodore de Have.

There was no religious architecture created in England during the 16th century, in part because of the break of Henry VIII with Rome. It is in the great country houses of the nobility that the Renaissance style is visible. Sir John Thynne, steward to the Lord Protector Somerset, designed several notable examples. The finest of these was his own house Longleat (1568–about 1580), on which he had the assistance of the mason Robert Smythson, who was to be the leading architect of the late 16th century. Except for the symmetry of the plan, arranged around two courts, there was little new in planning at Longleat, for the Tudor house was usually organized about a court. The typical English great hall at Longleat was an element derived from the hall (*q.v.*) of the medieval castle, and retained in English architecture through the 16th century. The main entrance of the house opens directly into one end of the great hall, but a low screen at the end of the hall, topped by a musicians' gallery, forms a passageway. In elevation Longleat is a long horizontal building with a wealth of windows; it is one of the most open secular buildings in Europe of the 16th century. There is a rectangular quality about the whole exterior, which is characteristic of English architecture; it is augmented by the repeated use of the bay-window unit. There are now three stories on the exterior, with the correct classic superimposition of the Doric order on the ground floor and Ionic and Corinthian orders above, but the third story was probably added after Thynne's death in 1580, replacing a pitched roof and dormers.

Robert Smythson, who aided Sir John Thynne at Longleat, went on to design and build several notable houses, the finest being Wollaton hall (1580–88) near Nottingham. On his tomb Smythson is called "architector and surveyor," not merely a mason. Wollaton has a magnificent site set up on a small hill overlooking a large park. The plan of the house is a square with four, square, corner towers, resembling a plan in the treatise on architecture by the Italian architect Serlio, whose book was influential in English Renaissance architecture. The great hall is in the centre of the square; it rises an extra story above the whole building. The house has a low basement story that contained the kitchens and service rooms; it is one of the first buildings to use this arrangement, which became common in the history of later English and American architecture. On the exterior the massing is that of rectangular blocks, whose rectilinear quality is further emphasized by the numerous many-mullioned rectangular windows. The decoration is completely classic with superimposed pilasters, round arched niches and classic balustrades, but it shows touches of Italian Mannerism, which came into England primarily from Flanders. The pilasters and half columns have raised bands across their middles, and the gables crowning the corner towers are decorated with Flemish strapwork (*i.e.*, bands raised in relief assuming curvilinear forms suggestive of leather straps).

Other examples of this style are Hardwick hall (1590–97) in Derbyshire, probably by Smythson; Kirby hall (about 1570–78) in Northamptonshire, perhaps by the mason Thomas Thorpe; and Montacute house (1588–1601) in Somerset.

With the possible exception of Robert Smythson, there were no important professional architects in England during the latter half of the 16th century. Once the surveyor John Thorpe was considered the most prominent architect of the period, Wollaton hall and Kirby hall being attributed to him as well as most of the other notable houses. This opinion was based on the discovery of his notebook of 280 drawings illustrating all these houses, but investigation proved that it was merely a collection of representations of all the famous buildings of the time. It is possible that Thorpe intended to prepare a book with representative examples of English architecture very much in the manner of the book prepared in France by Androuet du Cerceau. There were, however, some designs by Thorpe himself. One for his own house, presumably never built, was based in plan on his own initials I and T, and has the playful, abstract, unreal quality of Mannerism.

torians of the time to mark the Renaissance, or rebirth, of the humanistic spirit of classical antiquity. The "barbaric and benighted" centuries that intervened were then designated the middle ages. These three centuries did indeed witness a change in the intellectual and aesthetic climate of Europe, spanning as they did the time from Thomas Aquinas to Descartes, Dante to Tasso, Chaucer to Milton, Giotto to Michelangelo, Gothic to baroque. According to these humanistic writers the Renaissance originated in Italy and spread throughout Europe whenever and wherever Italian influence was felt; the period marked a revival of classical learning in the Greco-Roman manner; and there was a sharp shift from otherworldly religiosity to worldly psychology.

To accept such assertions uncritically would be highly misleading. All of Europe was undergoing a conscious departure from the prevailing standards of the middle ages. In the north the transition was not so abrupt as in Italy, but it came about nonetheless decisively as the age of scientific discovery overcame the medieval heritage of mysticism and superstition and brought about a new attitude toward life. Through the works of such artists as Grünewald, Dürer, Cranach and Holbein men saw their environment through different eyes. If the change occurred more suddenly and explosively in Italy than elsewhere, it was perhaps because that country was closest to the Roman tradition in letters, building and crafts, all of which had never really died out, and because the Gothic, a northern style, was never particularly compatible with the sunny south and the volatile temperament of its people. Virgil and other Roman authors had continued to be read during the middle ages, and scholarship and learning can hardly be said to have languished in medieval universities. Ionic and Corinthian capitals appear quite regularly in Romanesque and Gothic architecture, classical molding ornaments (egg-and-dart, leaf-and-tongue) are frequently found, and Gothic sculptural figures are clothed in graceful classical flowing drapery (*see* GOTHIC ART.)

While an increasingly secular spirit was apparent in the Renaissance, the majority of important buildings were still churches; statuary, paintings and music continued to be mainly religious in orientation.

In longer perspective, then, the Renaissance appears to be more a fermentation of ideas and a reorientation of scholarly and aesthetic thought than a rediscovery of ancient values and viewpoints. The period expressed itself in new ways, created new forms, invented new modes of representation and eventually arrived at a new understanding of the world. For convenience these tendencies can be grouped in such categories as Renaissance humanism, individualism and scientific naturalism.

Humanism.—It is a truism that every era finds what it wants in the classics. In literature and philosophy western Europe during the Renaissance veered away from a largely Roman orientation toward an inclusion of Greek studies, particularly the works of Homer and Plato. In Latin, however, humanists sought inspiration and models in the classical style of Cicero, Lucretius, Virgil and Tacitus rather than in the writings of the medieval church fathers. More broadly the humanists placed increasing

emphasis on man and his values, especially the dignity of man as realized in the study of the humanities rather than scholastic theology.

In architecture, humanism resulted in the study of Vitruvius' ancient treatises and in the careful measurement and observation of the surviving ancient monuments. The consequences can be seen in Brunelleschi's Pazzi chapel in Florence, which is a model of spatial clarity, crisp contours and the elegant use of classical decorative detail. The new architecture, as exemplified in the works and writings of Alberti, Bramante and Palladio, reveals the correct yet imaginative use of the classical orders and an eye for just proportions. In design, humanism resulted in the turning away from medieval variants of such classical motives as acanthus leaves, Ionic volutes, bead-and-reel patterns toward more authentic versions based on the study of ancient examples. In painting it resulted in the study of Euclid's geometry for the mathematical laws of linear perspective, as well as the exploration of themes drawn from classical literary and mythological sources. In sculpture humanism resulted in calm classical stances, figures clothed in authentic Roman togas and the rediscovery of the expressive power of the nude as revealed in the works of Donatello and Michelangelo.

Individualism.—One manifestation of humanism was the establishment of man as the measure of all things. Such works as Pico della Mirandola's essay on the *Dignity of Man,* Machiavelli's *Prince* and Castiglione's *Courtier* emphasized the personal, political and social importance of man. Churches began to come under the direct patronage of individual families and to bear the names of their donors, as, for instance, the Scrovegni chapel in Padua, built and decorated by Giotto; the Brancacci chapel in Florence with murals by Masolino da Panicale and Masaccio; and the Church of S. Lorenzo in Florence with the Medici chapel by Michelangelo. Portraiture in painting assumed a position of major importance, and self-portraits by artists often were given considerable prominence in their religious and historical pictures. The social position of major individual artists was upgraded from that of an artisan to a place almost on a plane with that of their patrons. Leonardo da Vinci insisted that painting, sculpture and architecture were truly liberal arts, and Michelangelo took pains to point out that he worked more with his brains than his hands. Individual artists became acutely conscious of their personal fame; many achieved sufficient renown to become the subjects of biographies, such as those in Vasari's *Lives of the Most Eminent Painters, Sculptors and Architects,* and Benvenuto Cellini wrote an account of himself in his celebrated *Autobiography.*

Scientific Naturalism.—In late Gothic sculpture, manuscript illuminations and tapestry designs there was a decreasing interest in allegory and moral preachments and an awakening to the beauties and delights of nature for their own sake. Artists began thinking more in terms of aesthetic problems than religious revelations. As with the nominalistic philosophy of William Ockham, personal observation was in ascendancy over the authoritarian view of scholasticism, interest in the natural world began to override that in the supernatural, and symbolism was superseded by accurate representation. A plant, in other words, was a plant, not a symbol of the a priori universal idea of plant as it existed in the mind of God, and the rendering of particular flora and fauna was based on nature. This visual revolution opened new vistas to Renaissance artists who proceeded to investigate optics, the mathematical bases of perspective drawing, the rational proportions of the human body, all with the idea of achieving a more natural way of representing the world of appearances. This phase of the Renaissance reached a climax in the scientific studies of Antonio Pollaiuolo and Verrocchio, who dissected cadavers in order to render more accurately the bone and muscle structure of the human body in action. It was this heritage they bequeathed to Leonardo da Vinci, whose *Notebooks* give evidence of his overwhelming interest in science.

The disintegration of Renaissance art is first apparent in the work of the Mannerists of the middle and late 16th century. The term Mannerism (*q.v.*) was coined to describe the work of certain artists who departed from accepted Renaissance ideals and emulated the manner rather than the spirit of the great masters—Leonardo, Michelangelo and Raphael. Mannerism had its origin in the psychological conflicts of the later works of the masters themselves, especially Michelangelo, who was torn between the pagan, Platonic ideal of classical beauty and the vigorous reaffirmation of traditional Christianity as exemplified in the Counter-Reformation movement.

Michelangelo's Mannerism is expressed in the twisting, turning, writhing bodies of his slave figures for Julius II's tomb and in the implausible positions of the figures atop the Medici tombs, as well as in the brooding melancholy and resignation of the late "Pietà." In his architecture it is found in the Laurentian library where the eye is led simultaneously in divergent directions, where there prevails a juxtaposition of discordant elements rather than a harmonious reconciliation of opposites and where there is a deliberate violation of the canons of proportion.

Later Mannerist artists became the first to work largely within the shadow of the giants of the immediate past. Since they could not excel their predecessors either in technique or in grandeur of expression, they could only adopt some of their vocabulary and use it to startle the spectator and produce the unexpected. Tintoretto and Caravaggio performed daring feats of foreshortening, devised surprising multiple-perspective effects, and used chiaroscuro to create dramatic spotlighting. Parmigianino's "Madonna With the Long Neck" reveals human figures with exaggerated oval faces, tapering fingers and willowy bodies. The sculptural equivalent is seen in the elegant elongation and winsome stance of Benvenuto Cellini's "Nymph of Fontainebleau," and in the airy grace and precarious balance of Giovanni da Bologna's bronze figure of "Mercury in Flight." The stage was thus set for the emergence of a new style, the baroque.

(WM. F.)

RENAN, ERNEST (1823–1892), French historian and philosopher whose thought anticipated both the existentialist anguish and the totalitarian messianism of the 20th century, was born on Feb. 28, 1823, at Tréguier, Côtes-du-Nord, of peasant stock. Educated at the ecclesiastical college in Tréguier, he began training for the priesthood. In 1838 he was offered a scholarship at the seminary of Saint-Nicolas-du-Chardonnet, whence he went on to that of Saint-Sulpice. There, however, he soon became involved in a crisis of faith which finally led him, reluctantly, to leave the Roman Catholic Church in 1845 because, in his view, the church's teachings were incompatible with the findings of historical criticism. But he kept a quasi-Christian faith in the hidden God, revealed to him both by Pascal's writings and by experience, as well as in himself as a kind of intellectual messiah.

1848 and Italy.—For Renan the February Revolution of 1848 was a religion in the making. Sometimes enthusiastic, sometimes critical, he participated in its messianic expectations and carried this ambiguous attitude over into *L'Avenir de la science*—a work which, in allusion to Descartes, he called his "Discourse on Method." The main theme of this work, not published till 1890, is the importance of the history of religious origins regarded as a human science having equal value to the sciences of nature. Something of an anticlerical though he now was, the French government sent him in 1849 to Italy to help classify manuscripts previously inaccessible to French scholars. In Rome, he was transformed, for a while, from an austere scholar into an artist alive to the pageantry and naïveté of popular religion.

The Second Empire.—Renan returned to Paris in 1850 to live with his sister, Henriette, on her savings and the small salary attached to his own post at the Bibliothèque Nationale. He began

to make a name for himself, with his doctoral thesis *Averroès et l'Averroïsme* (1852), then with two collections of essays, *Études d'histoire religieuse* (1857) and *Essais de morale et de critique* (1859), first written for the *Revue des Deux Mondes* and the *Journal des Débats*. The *Études* inculcated into a middle-class public the insight and sensitivity of the historical, humanistic approach to religion. Many of the *Essais* denounce the materialism and intolerance of the Second Empire in the name of Renan's aristocratic ideal: the intellectuals, acting as "bastions of the spirit," must, he affirms, resist tyranny by the intellectual and spiritual refinement, that is, the humanism exemplified throughout these essays.

In 1856 Renan proposed marriage to Cornélie Scheffer, niece of the painter Ary Scheffer. When Henriette discovered that to her brother she herself was less important not only than his work but even than another woman her jealousy knew no bounds. As related by Renan with more art than truth in his tribute to her (1862), she gave way to his benevolent egoism and agreed to live with him and his wife. Yet the beginnings of his marriage were unhappy, the more so as he was still dependent on Henriette's savings.

In October 1860 Renan was entrusted with an archaeological mission to the Lebanon. The Phoenician inscriptions which he discovered were published in his *Mission de Phénicie* (1864–74). They were later included in the *Corpus inscriptionum semiticarum*, which he helped to bring out through the Académie des Inscriptions et Belles-Lettres. But archaeology was not his main interest. In April 1861, with his wife and sister, he visited the Holy Land in search of materials and inspiration for the life of Jesus which he was bent on writing. He finished a first draft of it in the Lebanon but at tragic cost, for Henriette died of malaria at Amschit on Sept. 24, 1861, while he himself fell desperately ill.

Renan had counted on his life of Jesus to secure election to the chair of Hebrew at the Collège de France. He was elected, before the book was ready, on Jan. 11, 1862. But in his opening lecture, on Feb. 21, he referred to Jesus in Bossuet's words as "an incomparable man." While this was in his eyes the highest praise one could bestow on a man, it was not enough for the clericals, who took advantage of its implied atheism and the uproar caused by the lecture to have Renan suspended. Contemptuously refusing an appointment to the Bibliothèque Impériale (June 1864), Renan decided for the next few years to live by his pen. In fact, he had to wait till 1870 before the chair was restored to him. He was thus pushed into opposition, but had already begun to frequent such dissident salons as that of Princess Mathilde (*see* BONAPARTE) and such literary notables as Flaubert, Sainte-Beuve, Taine, and the Goncourt brothers.

When the *Vie de Jésus* did appear (June 1863) it was virulently denounced by the church. While not Renan's best historical work, it can still claim the attention of 20th-century readers because it presents a "mythical" account of the making of Christianity by the popular imagination and so has a place, like his other historical works, in the literature of messianism. After a journey in Asia Minor in 1864–65 with his wife he published *Les Apôtres* (1866) and *Saint Paul* (1869), to follow the *Vie de Jésus* as parts of a series, *Histoire des origines du christianisme*. Both these volumes, largely by brilliant descriptions of how Christianity spread among the rootless proletariat of the cities of Asia Minor, illustrate his preoccupation with the question: would the intellectuals of the 19th century lead the masses toward a new enlightenment?

The Franco-German War and the Third Republic.—Renan began to interest himself increasingly in politics. In 1869, at the beginning of the "liberal" phase of the Second Empire, he stood unsuccessfully for parliament. In the same year he defended constitutional monarchy in an article, "La Monarchie constitutionnelle en France." So far he was a liberal. In the same spirit he tried during the Franco-German War of 1870–71 to work across frontiers: he corresponded with David Strauss and tried to persuade the Prussian crown prince (later German emperor as Frederick III) to stop the war. But the bitterness of France's defeat and his anger with democracy turned him authoritarian. Thus *La Réforme intellectuelle et morale* (1871) argues that France, to achieve national regeneration, must follow the example set by Prussia after the Battle of Jena in 1806. But by taking his advice France would have become the sort of clerical monarchy which Renan soon found he did not want. He had to resign himself to the Third Republic but withdrew from public life. While he continued to travel zestfully all over Europe, visiting surviving Bonapartists such as Prince Jérôme Napoléon, his life became more and more identified with his writings. He was elected to the Académie Française in 1878.

Renan's ironical yet imaginative vision of the "festival of the universe" found expression in *L'Antéchrist* (1873; vol. iv of the *Histoire des origines*), with its satirical portrait of Nero and its apocalyptic atmosphere assuredly the most impressive of his historical narratives. The "festival of the universe" provides a visionary end to the *Dialogues philosophiques* (1876). In the first of these, however, Renan is more ironically skeptical about the hidden God than he had been. In fact, the "epicureanism" of his later years masks an anxiety about death and the hereafter. His more superficial side is illustrated in the "philosophic dramas" (collected edition 1888) which trace his acceptance of the Republic, especially *Caliban* (written 1877) and *L'Eau de Jouvence* (written 1879). In the former, the aristocracy (Prospero and Ariel) loses to democracy (Caliban) because alchemical spells (traditional sanctions) are powerless against a people infected by positivism; scientific power politics would be an effective answer, but this is out of the question because in practice it would mean a clerical monarchy. The moral of *Caliban* is therefore: rather a republic than the church.

As to the remaining volumes of the *Histoire des origines*, if Renan's "epicureanism" is hard to find in *Les Évangiles* (1877) it is present in *L'Église chrétienne* (1879), in the portrait of Hadrian; but in *Marc-Aurèle* (1882) the study of Marcus, again a self-portrait, is dominated by the author's preoccupation with death. Since 1876 Renan had been working on his memoirs, *Souvenirs d'enfance et de jeunesse* (1883), in which he reconstructs his life so as to show that he was predestined to become a *prêtre manqué* (failed priest) and that, in spite of heavy odds, his wager on the hidden God had "paid off" in terms of happiness.

In the *Souvenirs* Renan is too serene for some tastes, though his irony keeps his complacency in check. In *L'Ecclésiaste* (1882) and two articles on Amiel (1884), he is above all an ironist combating the Pharisees. On the other hand, in some of his speeches at the Académie Française, on Claude Bernard (1879) and Émile Littré (1882), he reveals his anguish in moments of doubt. Thus he manifests a baffling variety, but the moral heart of the man is to be found in one of the later dramas, *Le Prêtre de Nemi* (1885), and above all in his *Histoire du peuple d'Israël* (1887–93). For him, the history of Jewish messianism bore witness to man's capacity for faith when the odds are against him. Thus it revived his own faith. He could therefore hope that, though Judaism would disappear, the dreams of its prophets would one day come true, so that "without a compensatory Heaven justice will really exist on earth." Having exhausted himself in an effort to finish the work, he died shortly after its completion on Oct. 2, 1892.

With his leanings toward liberalism and authoritarianism in politics, faith and skepticism in religion, Renan embodied the contradictions of the middle class of his time. Politically, his influence after his death was far-reaching, on nationalists like Maurice Barrès and Charles Maurras, on republicans like Anatole France and Georges Clemenceau. He succeeded in assuaging one of the great anxieties of his time, the antagonism between science and religion, but he felt this anxiety himself.

Henriette Psichari's definitive edition of Renan's works appeared in ten volumes in 1947–61.

RENARD, JULES (1864–1910), French writer, best known for *Poil de Carotte* (1894; English translation, *Carrots*, 1946), a bitterly ironical account of his own childhood, in which a grim

humour conceals acute sensibility. All his life, although happily married, and the father of two children, he was haunted by, and tried to hide, the misery he had suffered as a child from lack of affection.

He was born at Châlons-sur-Mayenne on Feb. 22, 1864, and educated at Nevers and in Paris. After his marriage in 1888, he devoted himself to writing. First and foremost an artist (he described himself as a *"chasseur d'images"*), he was one of the first French writers to make use of significant detail in descriptive writing. His sketches of animal life in *Histoires naturelles* (1896) are models of their kind. Although he spent most of his life in Paris, he never lost touch with his native countryside, and in *Les Philippe* (1907), and *Nos frères farouches* and *Ragotte* (both 1908), he depicted rural life with amused penetration and cruel realism. He also wrote plays, including a dramatized version of *Poil de Carotte* (1906). He was a founder member of the *Mercure de France* (1900), and was elected to the Académie Goncourt (1907). He died in Paris on May 22, 1910. His *Journal* (English translation, 1964), 17 volumes (1925–27), by F. Bernouard, is essential to a full understanding of his personality.

RENARD THE FOX: *see* REYNARD THE FOX.

RENART, JEAN (fl. 1200–1222), French author of romances of adventure (*romans d'aventure*) distinguished by their stylistic originality, is associated with the village of Dammartin en Goële, near Meaux. The attribution to him of two long poems, each surviving only in a single copy, was a major literary discovery of the 1890s—an age strikingly attuned to his mood and style. Joseph Bédier drew attention to his personality in his Fribourg edition of the *Lai de l'Ombre* (1890), and the possibility of his authorship of *L'Escoufle* and *Guillaume de Dôle* was first mooted by Paul Meyer in his edition of *L'Escoufle* in 1894. Erudite stylistic analysis by A. Mussafia (1896–97), F. M. Warren (1908), and G. Charlier (1910) provided confirmation, and in 1913 Bédier discovered anagrams on the name RENART in the final lines of both romances.

L'Escoufle ("The Kite") is a picaresque novel in verse, dedicated to Baldwin VI of Hainaut, later, as Baldwin I, emperor of Constantinople. The betrothed children, Guillaume and Aelis, flee to France from their tutelage at the emperor's court; near Toul they are separated when Guillaume pursues a kite (hawk) which has stolen his mother's ring. Aelis becomes a seamstress, Guillaume an ostler and falconer. One day he tears out the heart of a kite and devours it, and this symbolic gesture leads to their reunion. *Guillaume de Dôle*, dedicated to Miles of Nanteuil, is the old tale of the calumniated bride: Guillaume's sister Lienor, on the eve of her marriage to the emperor, is slandered by the seneschal who, posing as her lover, describes a rose-shaped birthmark on her thigh (whence the poem's other title, *Le Roman de la Rose*). She appears disguised and accuses him of ravishing her: subjected to an ordeal, he sinks to the bottom of a holy water stoup, thus vindicating himself, but also invalidating his previous story! The *Lai de l'Ombre* is a brilliant *marivaudage* (*i.e.*, a piece of elegant verse, artificial and witty in style): a knight presses a ring on his lady and when she refuses it throws it to her reflection (*ombre*) in a well in a gesture that persuades the lady to accept him.

Renart, both realistic and *précieux* (mannered in style), eschews the fey atmosphere and serious morality of his predecessor Chrétien de Troyes (*q.v.*) in favour of half-nostalgic, half-flippant portrayal of high society—the *dîner sur l'herbe* (idyllic picnic), the bathing in the spring, the exchange of girdles and rings, the tourneying and luteplaying far into the night. His colloquial syntax and blend of elegant sentiment with interspersed quips and proverbial wit convey an authentic impression of idiosyncratic poetic temperament. *See* also ROMANCE.

RENAUD DE MONTAUBAN (or LES QUATRE FILS AYMON), the title of an old French *chanson de geste*, the theme of which long survived in chapbooks and ballads throughout Western Europe. Renaud slays Charlemagne's nephew Bertolai after a quarrel over chess. He mounts his marvelous steed, Bayard, which understands human speech, and, with his brethren, barricades himself in the rock-fortress of Montessor (at the confluence of the Semoy and the Meuse, near Sedan, still known as *La Montagne des quatre fils Aymon*). Their father Aymon helps to besiege them.

Later they hold out in Montauban as the allies of King Yon of Gascony, assisted by their cousin, the sorcerer Maugis. Finally they escape to Dortmund in Westphalia; Renaud turns to a life of religion and helps to build Cologne Cathedral, refusing any wages, and is slain by his envious fellow-workmen. His body, thrown into the Rhine, floats upstream conducted by choirs of angels, and is buried in state at Dortmund.

This story may contain elements of prehistoric myth, combined with traditions relating to Charles Martel's conflict with Eudes (Odo) of Aquitaine in 718–720 (*cf. Mainet*, another of the Charlemagne legends, *q.v.*). Such tales were rooted in the soil of Frankish Austrasia, and on to them were grafted hagiographic legends of the archdiocese of Cologne.

The French poem has more than 18,000 lines; a Middle Dutch poem of similar length (*Renout von Montalbaen*) is the ancestor of the early-17th-century German *Volksbuch*, or chapbook, version. The Spanish Reinalte or Reinaldos, of the *romancero* (*see* SPANISH LITERATURE: *Romancero*) and Lope de Vega's play, derives partly from French epic sources, partly from the numerous Italian Rinaldo poems (from the 14th century to Tasso's first epic, *Il Rinaldo*, 1562). The theme is kept alive by the ballad-singers of Naples and the puppet plays of Liège.

RENAUDOT, THÉOPHRASTE (1586?–1653), French physician, philanthropist, father of French journalism, and friend of Richelieu, was born at Loudun. He studied surgery in Paris and received the degree of doctor at Montpellier.

In 1612 Richelieu summoned him to Paris to organize a scheme of public assistance. In 1630 Renaudot, as commissary general of the poor, opened in Paris a *bureau d'adresse*—a combined labour bureau, intelligence department, exchange, and charity organization, which directed indigent sick persons to doctors prepared to give them free treatment. He established (1635) a free dispensary despite the opposition of the ultraconservative medical faculty in Paris, which refused to accept the new medicaments he proposed and restricted themselves to the old prescriptions of bloodletting and purgation. Under the protection of Richelieu, Renaudot started the first French newspaper, the *Gazette* (1631; *see* NEWSPAPER). In 1637 he was authorized to add pawnbroking to the activities of the *bureau*, and the first pawn shops were opened.

The medical faculty campaign against Renaudot, headed by Guy Patin, was prosecuted with increased vigour after the deaths of Richelieu and Louis XIII, and eventually he was denied the right

to practise medicine in Paris. The *Gazette* remained to him, however, and in 1646 he was appointed by Mazarin historiographer to the king. Renaudot died on Oct. 25, 1653.

RENDERING, ARCHITECTURAL: *see* ARCHITECTURAL RENDERING.

RENÉ I (1409–1480), French prince who was titular king of Naples from 1435 to 1442 and duke consort of Lorraine from 1431 to 1453, but whose more permanent authority was confined to Bar, Anjou, and Provence. He was born at Angers on Jan. 16, 1409, the second son of Louis II, duc d'Anjou (*see* LOUIS, kings of Naples), and Yolande of Aragon.

On his father's death (1417), René's elder brother, Louis III, succeeded to Anjou, Maine, and Provence (*qq.v.*); but in 1419 his maternal granduncle, Duke Louis of Bar, named René as his successor (*see* BAR, COUNTS AND DUKES OF). In 1420, moreover, René married Isabella, elder daughter of Charles II (*q.v.*) of Lorraine. Sole ruler of Bar from 1430, he claimed Lorraine by right of his wife on Charles II's death (1431). Charles VII of France, husband of René's sister Mary, supported this claim, but Antony (Antoine) of Vaudémont contested it (*see* LORRAINE).

Antony defeated René at Bulgnéville (July 2, 1431), took him prisoner, and handed him over to Philip (*q.v.*) the Good, duke of Burgundy. Released on parole (May 1432), after giving his sons John (1426–70) and Louis (1427–43) as hostages, René in 1433 agreed that his elder daughter Yolande (1428–83) should marry Antony's son Ferry; but in 1434, when the Holy Roman emperor Sigismund had recognized René as duke of Lorraine (April) and when René had also inherited Anjou and Provence from Louis III (November), Philip took umbrage and, in December, summoned René back into captivity. René finally obtained his discharge on Jan. 28, 1437, promising a heavy ransom and making territorial concessions.

Meanwhile Joan II (*q.v.*) of Naples, who died in February 1435, had made René her heir (*see* also NAPLES, KINGDOM OF). After further conciliating Burgundy by the marriage of his son John, now styled duke of Calabria, to Philip's niece Mary of Bourbon (d. 1448), René in spring 1438 sailed for Naples, which his wife Isabella had been defending against his rival Alfonso V of Aragon. Besieged in Naples by Alfonso from November 1441, he abandoned the city in June 1442. In October he was back in Provence.

From the 1420s the English (*see* HUNDRED YEARS' WAR) had been occupying Maine. To recover it for his younger brother Charles, René took part in the Anglo-French negotiations begun at Tours in April 1444. These led to the marriage of his younger daughter Margaret (of Anjou; *q.v.*) to the English king Henry VI in 1445, but Maine had eventually to be won back by force of arms (1448). Meanwhile Charles VII of France had helped René to pacify Lorraine (war of Metz, 1444–45), and the long-planned marriage of Yolande and Ferry had been solemnized (summer 1445). René accompanied Charles VII on his victorious campaigns of 1449–50 against the English in Normandy. On Isabella's death (Feb. 28, 1453), her duchy of Lorraine passed to John of Calabria.

René's expedition to Lombardy (1453–54), to help Milan and Florence against the Venetians in the hope of a subsequent invasion of Naples, was frustrated by reconciliation between the Italian belligerents. In March 1454 he married Jeanne, daughter of Guy XIV de Laval (*see* LAVAL). Thereafter, apart from important measures for the economic development of Provence, which also benefited from legal reforms under him, he concerned himself more with the arts and literature in Anjou (at his residences at Ponts-de-Cé and at Chanzé, near Angers) and in Provence (at Aix, Tarascon, Marseilles, Peyrolles, and Pertuis) than with dynastic ambitions, which he left to the energetic John of Calabria. In 1466, however, he accepted the title of king of Aragon and count of Barcelona from the Catalan rebels against John II of Aragon. With Louis XI of France his relations were generally strained; and in 1476 Louis forced him to forswear any alliance with Charles the Bold of Burgundy, the French king's great opponent. René died at Aix-en-Provence, on July 10, 1480.

René has been credited with numerous paintings, often simply because they bear his arms. These works, generally in the Flemish style, were probably executed at his behest by the painters whom, together with sculptors, goldsmiths, and tapestry workers, he maintained at his courts. The "Burning Bush" triptych by Nicolas Froment, at Aix, portrays René and Jeanne de Laval.

René's writings, or works at least inspired by him (collected edition by the comte de Quatrebarbes, 1843–46), include a treatise on tournaments; an idyllic poem, *Regnault et Jehanneton* (on his courtship of Jeanne); a mystical dialogue, *Le Mortifiement de Vaine Plaisance* (edited by F. Lyna, 1926); and an allegorical romance, *Le Livre de Cuer d'amours espris*, otherwise entitled *La Conqueste de doulce Mercy* (edited by E. Winkler, three volumes, 1927).

RENÉE OF FRANCE (1510–1575), duchess of Ferrara, a French princess notable in the history of the Protestant Reformation, was born at Blois on Oct. 25, 1510, the second daughter of Louis XII of France and Anne of Brittany. She was married in 1528 to Ercole d'Este, who became duke of Ferrara as Ercole II in 1534 (*see* ESTE, HOUSE OF). In return for renouncing her claims on Brittany, she was granted the duchy of Chartres, the countship of Gisors, and the *châtellenie* of Montargis by Francis I of France.

Renée's court at Ferrara became a meeting place for liberal thinkers and a refuge for French Protestants. The humanist Olympia Morata was brought up there; Clément Marot (*q.v.*) found shelter there in 1535; and Calvin himself visited Renée in 1536. Under Calvin's influence she ceased practising Catholicism in 1540; but Pope Paul III in 1543 granted her a brief exempting her from all ecclesiastical jurisdiction save that of the Holy Office. Her husband, however, took her children away from her and, in 1554, allowed her to be sentenced to imprisonment for heresy; but within a few days she was set free after a form of recantation.

A widow from 1559 and on bad terms with her son, Alfonso II of Ferrara, Renée returned to France in 1560 and settled at Montargis, which she made a centre of Protestant propaganda. During the Wars of Religion her château was besieged by her son-in-law, François, duc de Guise, in 1562, and she was several times harassed by Catholic troops. She died at Montargis on June 12, 1575.

RENFREW, a southwestern county of Scotland, bounded on the north by the river and Firth of Clyde, on the east by Lanark county, on the south, southwest, and west by Ayr County, and on the northwest by the Firth of Clyde. Area 224.7 sq.mi. (582.0 sq.km.).

Physical Features.—The surface is low and undulating, except toward the Ayr border on the west, where the principal height is the Hill of Stake (1,711 ft. [522 m.]), and the confines of Lanark on the southeast, where a few points attain a height of 1,100 ft. (335 m.). The southwestern hills are formed of volcanic rocks, basalts, porphyrites, tuffs, and agglomerates of Calciferous Sandstone Age. Practically all the area northeast of these rocks is occupied by the Carboniferous Limestone series. Boulder clays and late-glacial silts and sands cover low-lying areas. Much of the higher land in the centre is well wooded. In the northwest Loch Thom (an artificial lake) and Gryfe reservoirs provide Greenock with water; to the southeast numerous lochs and reservoirs provide water, not only for Renfrew towns and industries, but also for parts of Ayr and Glasgow.

Apart from the Clyde (*q.v.*), the principal rivers are the White Cart, Levern, Black Cart, and Gryfe. Strathgryfe is the only large vale in the county; the scenery at its head is wild and bleak, but the lower reaches are pastureland. The wooded ravine of Glenkilloch to the south of Paisley is watered by Killoch Burn, on which are three falls.

The hills of Renfrew County are not of sufficient height to ex-

hibit the Scottish alpine flora found on nearby highland mountains. In summer the moors are yellow with tormentil and the gaily coloured mountain pansy. In autumn the uplands are purple with ling and heath. Milkwort and bog asphodel grow abundantly.

In those parts of the county which have not been industrialized, and so remain rural in character, are found all or most of the wild animals common to Scotland, such as bats, hedgehogs, moles, and shrews; foxes, stoats, weasels, and otters; hares, squirrels, rats, mice, and voles; lizards, adders, and vipers. Rabbits are not as common as formerly. There is a great variety and abundance of bird life, particularly seabirds and moorbirds. The numerous lochs and dams are favourite haunts of duck, teal, coot, moorhen, grebe, and gull.

History.—At the time of the Roman advance from the Solway the land was peopled by the British tribe of Damnonii. Forts at Bishopton and near Greenock were built by the Romans to prevent the outflanking of the Antonine Wall, but after the Romans retired (410) the territory was overrun by Cumbrian Britons and formed part of the kingdom of Strathclyde, extending from the River Derwent in Cumberland to the Clyde. It continued so until 1124 when Strathclyde was finally united to the Scottish crown under King David. In 1314 Walter Fitzalan, high steward of Scotland, who was settled in Renfrew, married Marjory, daughter of King Robert the Bruce and mother of Robert II. In 1404 Robert III erected the barony of Renfrew and the Stuart estates into a separate county which, along with the earldom of Carrick and the barony of King's Kyle (both in Ayr), was bestowed upon his son, afterward James I. From their grant are derived the titles of earl of Carrick and baron of Renfrew, borne by the eldest son of the sovereign.

Apart from such isolated incidents as the defeat of Somerled near Renfrew in 1164, the Battle of Langside in 1568, and the capture of the 9th earl of Argyll at Inchinnan in 1685, the history of the county is scarcely separable from that of Paisley or the neighbouring county of Lanark.

The village of Elderslie between Paisley and Johnstone was the birthplace (*c.* 1270) of Sir William Wallace, the Scottish national hero, and the inventor James Watt was born at Greenock in 1736.

Population and Administration.—The population in 1961 was 338,872; both Gaelic and English were spoken by 1,556 persons (Gaelic only, 6 persons). The large burghs are Paisley (pop. [1961] 95,750), Greenock (74,560), and Port Glasgow (22,559). The small burghs are Johnstone (18,434), Barrhead (14,421), Gourock (9,608), and Renfrew (17,945), the only royal burgh. There are five county districts.

The county returns one member to Parliament for the eastern division and another for the western. Paisley and Greenock each return one member. Renfrew county forms a sheriffdom with Argyll and there are two resident sheriffs-substitute at Paisley and one at Greenock. (CH. RO.)

The Economy.—The county is one of the most highly industrialized in Scotland, and more than half the employed population is engaged in manufacturing industries.

Above about 700 ft. soils are thin and often peaty. At lower levels soils improve, especially along the lower reaches of the Black and White Cart waters, where there are extensive stretches of alluvial loam, well suited to arable cultivation. The greater part of the farmland consists of clay soils, ideal for grassland farming. This, with the urban environment, makes Renfrew primarily a dairying county, supplying milk to its own towns and to Glasgow. Even upland farms produce milk, though their main incomes may come from sheep or cattle rearing. The chief crops, grass and oats, are grown for fodder; arable farms produce potatoes, wheat, and barley as cash crops. A number of small holdings specialize in horticulture, poultry, and pig-raising. Some igneous rocks are quarried for roadstone. Forestry is insignificant, and commercial fishing, for which several of the Clyde towns and villages were once famous, has virtually ceased.

Shipbuilding and marine engineering are the chief industries in Greenock and Port Glasgow (*qq.v.*); there are smaller shipyards in Paisley (*q.v.*). The county accounts for 40% of tonnage and 25% of marine engines built on the Clyde. Renfrew burgh has the biggest general engineering works. A smaller group of engineering industries, mainly in Johnstone (*q.v.*), specializes in heavy machine tools; mining and office machinery are manufactured at Greenock. Motor vehicles are made at Linwood; Renfrew also has one of the few electrical cable factories in Scotland.

There are thread mills in Paisley and carpets are made at Elderslie. Woolen yarn and knitted goods are produced in Greenock and ropes at Port Glasgow. Other industries include sugar refining at Greenock and corn flour and other food products at Paisley. Within the Landward part of the county there are, in addition to the automobile factories at Linwood, paper making also at Linwood, tanning at Bridge of Weir, and tire making at Inchinnan.

See H. A. Moisley and A. G. Thain (eds.), *The County of Renfrew,* Statistical Account of Scotland, third series (1962); Land Utilisation Survey of Britain, *Land of Britain,* parts 20–23, *Renfrewshire; Lanarkshire; Dunbartonshire and Stirlingshire,* by L. D. Stamp (ed.) (1946).
(H. A. M.)

RENFREW, a royal and small burgh and the county town of Renfrew County, Scot., near the south bank of the Clyde, 5½ mi. (8¾ km.) W by N of Glasgow by road. A small part of the parish of Govan is included in the burgh boundaries. Pop. (1961) 17,945. Industries include large shipbuilding works, engineering, and the manufacture of rubber and paint. The Clyde Trust has constructed a large dock and there is a ferry to Yoker. South of the town is the municipal aerodrome and civil airport. Robert III gave a charter in 1396, but it was a burgh (Renifry) at least 250 years earlier. Close to the town, on the site of Elderslie House, Somerled, lord of the Isles, was defeated and slain in 1164 by the forces of Malcolm IV, against whom he had rebelled. Robert III bestowed upon his son James (afterward James I of Scotland) the title of baron of Renfrew, still borne by the eldest son of the sovereign.

RENI, GUIDO (1575–1642), painter and engraver of the Bolognese school, the great precursor of neoclassicism, was born on Nov. 4, 1575, at Bologna. At the age of ten he entered the studio of Denis Calvaert, a Flemish painter. At 20 he was attracted by the anti-Manneristic novelty of the Carracci family and joined their "Academy of the Natural." In his early years Guido was not precocious. He trained himself by copying from Annibale Carracci, from plaster reproductions of classical pieces and from the St. Cecilia of Raphael. In 1599 he was received into the guild of painters. Between 1600 and 1601 Guido was in Rome, where a few years later he opened a studio of his own. The most important work to survive from this first period in Rome is the "Crucifixion of St. Peter" (Vatican). In 1604 Guido was in Bologna, collaborating in the painting of frescoes in the cloisters of S. Michele in Bosco. In 1607 he was back in Rome, sent for by Pope Paul V to paint the Vatican frescoes of the "Nozze Aldobrandine" and "Le Dame" (1608). He entered the service of Scipione Cardinal Borghese and painted for him the fresco "St. Andrew's Progress to the Gallows" (1608) in the chapel of S. Gregorio Magno al Celio and "The Eternal Father and the Minstrel Angels" in the chapel of Sta. Silvia. Guido surrounded himself with helpers—Lanfranco, Albani, Gessi, Antonio Carracci, Cavedone, Sementi—who were fascinated by his noble if somewhat tyrannical personality. The frescoes illustrating the stories of the Virgin in the pontifical chapel in Montecavallo (Palazzo Quirinale) date from 1610 and, though not the best known, are perhaps the most poetic of his frescoes. Following some quarrels with the pope's treasurer, Guido returned to Bologna; but, recalled to Rome by the pope himself in 1612, he finished some frescoes in the pontifical chapel of Sta. Maria Maggiore. Between 1613 and 1614 followed the celebrated fresco "Phoebus and the Hours, Preceded by Aurora" in the Borghese garden house (now Palazzo Rospigliosi). In 1614 Guido was again in Bologna and painted the fresco "The Glory of St. Domenic" in the church of the same name. From 1617 to 1621 he worked at the Mantuan court of Duke Ferdinand Gonzaga (four paintings of the "Labours of Hercules," now at the Louvre, Paris). In 1622 he went to Naples to paint the frescoes of the treasury of S. Gennaro, but, having quarreled with his patrons, he returned to Rome almost at once, leaving behind his pupils Gessi and Sementi, whom he had

CULVER SERVICE

"PHOEBUS AND THE HOURS, PRECEDED BY AURORA," FRESCO BY GUIDO RENI. IN THE PALAZZO ROSPIGLIOSI, ROME

employed the previous year for the painting of the frescoes in the Chapel of the Sacrament of Ravenna cathedral. The last documented visit to Rome is in 1627. He settled down in Bologna, where from around the year 1630 began a decade in which his art was shown to the greatest perfection, starting with the famous "Madonna With Rosary" (Bologna). He died on Aug. 18, 1642, in Bologna and is buried in S. Domenico.

Highly praised by his contemporaries and subsequently by all defenders of the Academy up to the neoclassicists, above all in France, Guido, like Raphael and the classicists, came under the condemnation of the romanticists and the epoch of Ruskin. By the middle of the 20th century art criticism had studied afresh Guido's personality, making a better appraisal of 17th-century "Academism," in a new historical perspective. In Rome, the main inspiration for Guido's art was the Raphael frescoes and the archaeological marbles, the Niobe and the Laocoön, and he stands apart from the baroque art of his day. His striving is toward a harmony of statuary, classical and elusive at the same time, in which reality is presented in idealized proportions. But since Guido works toward classicism in a period from which classical traits are absent, he remains isolated, far removed from the realistic optimism in Rome from which were to spring the baroque forms of art.

For Guido, the classical ideal becomes a feeling for beauty as the very stuff of poetry. The greatness of Guido lies in the manner in which he evokes the musical harmony of this myth of beauty, filling it with the altogether modern sentiment of nostalgia. The creative process is calm and serene, just as are the studied softness of colour and form. Guido's feeling of melancholy was, however, soon to become debased into sentimentalism and mannerized religiosity.

Other major works by Guido Reni are to be found in the galleries and churches of Bologna, Rome, Naples, Siena and Crema in Italy, in the Louvre, Paris, in the National gallery, London, at Dulwich, London, and in the Kunsthistorisches museum, Vienna.

RENKUM, a municipality of the Netherlands, situated 2½ mi. W of Arnhem (*q.v.*) on the Utrecht road and comprising the villages of Oosterbeek (the local government centre), Renkum, Doorwerth, Heelsum, and Wolfheze. Pop. (1960) 29,095 (mun.). Area 18.3 sq.mi. (47.4 sq.km.).

A tourist and international conference centre in beautiful surroundings, it was especially associated with the Battle of Arnhem in World War II; on the Oosterbeek village green is the Airborne memorial put up by the Dutch in memory of the British airborne forces. The Arnhem-Oosterbeek war cemetery is outside the town and Castle Doorwerth is now the Airborne Museum. Renkum is linked by road and rail with main towns. Local industries include rubber, paper, and brickmaking.

RENNELL, JAMES (1742–1830), the leading British geographer of his time, was born at Chudleigh, Devon, on Dec. 3, 1742. He served in the Royal Navy from 1756 to 1763, becoming an expert marine surveyor. Proceeding to India in 1760, Rennell in 1762 was lent to the East India Company as assistant to Alexander Dalrymple (*q.v.*) on a voyage to the Philippine Islands. He joined the company and became surveyor general in Bengal (1764) and after 1767 was surveyor general also of Bihar and Orissa. Until he left India in 1777 he was responsible for producing numerous local and provincial maps. His *Bengal Atlas* (1779) was several times reissued and was reprinted in 1911. Five editions of his *Memoir of a Map of Hindoostan* appeared between 1783 and 1793; the map itself was first published in 1782. A paper in the *Memoirs* on the Ganges and Brahmaputra rivers became a valuable source to geographers and geologists. Rennell wrote works on Herodotus, the Plain of Troy, and the expedition of Cyrus II the Great, and also a *Comparative Geography of Western Asia* (1831). As adviser to the African Association he produced papers and maps on West Africa. His work on oceanography included several papers on the English Channel and a book on ocean currents (1832). By his vast industry and wide range Rennell acquired an international reputation. He died in London on March 29, 1830, and was buried in Westminster Abbey.

RENNER, KARL (1870–1950), Austrian statesman, first chancellor of the first republic and first president of the second, was born on Dec. 14, 1870, the son of a peasant, at Dolni-Dunajovice (Unter-Tannowitz), Moravia (Czechoslovakia). He studied law at the University of Vienna and early attached himself to the Social Democratic Party. He advocated the transformation of the Habsburg Empire into a federal democratic commonwealth based on equal political and cultural rights for all nationalities. He was elected deputy to the Austrian *Reichsrat* (parliament) in 1907 and, after the collapse of the empire, he

became, on Nov. 12, 1918, the first chancellor of the Austrian Republic. He then supported the idea of a union of Austria with a democratic federal Germany. Renner was largely responsible for the decrees of the *Nationalrat* (lower chamber) which called for the dethronement of the dynasty of Habsburg-Lorraine and the banishment of all members of this house if they did not submit entirely to the laws of the republic, and he was in charge of the negotiations which led to the former emperor Charles's leaving Austria in March 1919. On May 12, 1919, Renner went to Paris as head of the Austrian delegation and, after the resignation of the foreign minister, Otto Bauer (*q.v.*), signed on Sept. 10, 1919, the Treaty of St. Germain by which Austro-German union (*Anschluss*) was prohibited.

The first coalition ministry had been succeeded in October 1919 by a second, in which Renner was again chancellor and secretary for foreign affairs. Renner, who as a Social Democrat was inimical to the nationalist Hungarian government, refused to grant demands put forward to extradite the Hungarian revolutionaries who had fled to Vienna. This brought him into conflict with the Christian Democrats and their representatives in the cabinet. The coalition dissolved on June 11; but Renner remained in charge of foreign affairs until Oct. 22, 1920. When in 1930 the Social Democrats became the stronger party, Renner was elected president of the *Nationalrat;* he resigned in 1933. After the annexation of Austria to Germany in 1938, Renner remained unmolested. In a public statement a few days before the plebiscite of April 10, 1938, he had recalled that he had already supported the *Anschluss* idea in 1918.

After the occupation of Vienna by the Soviet Army, Renner obtained approval from the Russians for the formation of an Austrian democratic government and on April 29, 1945, became chancellor of the second Austrian Republic. On Dec. 20, 1945, the newly elected *Nationalrat* nominated him president of the republic. He died at Doebling, near Vienna, on Dec. 31, 1950.

His principal works are *Grundlagen und Entwicklungsziele der Österreichisch-ungarischen Monarchie* (1904); *Österreichs Erneuerung,* three volumes (1916–17); *Die Wirtschaft als Gesamtprozess und die Sozialisierung* (1924). His memoirs (*An der Wende zweier Zeiten*) appeared in 1946. (A. F. P.; X.)

RENNES, a town in the *département* of Ille-et-Vilaine, western France, formerly the capital of Brittany, lies at the confluence of two rivers, the Ille and the Vilaine, in the centre of a basin that opens widely on the outer reaches of Normandy, Maine, Anjou and lower Brittany. Pop. (1962) 145,013.

The town is built on a regular plan, the main axis running east and west along the canalized Vilaine. The plan originated in the reconstruction after the great seven-day fire of 1720 which destroyed the best part of the old town, but spared the magnificent house of the parliament of Brittany, the work of Salomon de Brosse, finished in 1654. It was to the credit of Jacques III Gabriel, the king's architect (whose son designed the Place de la Concorde in Paris) sent down to supervise the plans, that he achieved the harmony of the centre with the house of parliament, with a remarkable austere coherence. Also by Gabriel is the town hall, a very gracious edifice in the Louis XV style. The cathedral was partly rebuilt at the beginning of the 19th century, its most interesting element being a 15th-century gilt carved wood altarpiece of German work.

Other interesting architectural remains, all on the northern bank of the river, are the Mordelaise gate (15th century) and the cluster of 16th-century houses and 17th-century mansions in the narrow, crooked streets round the cathedral. No building of architectural value suffered from the extensive damage caused by World War II, except the interesting late Gothic church of Saint-Germain. The museum building, destroyed by enemy action in 1944, may now be considered one of the most modern provincial museums in France, the most interesting exhibit being a Nativity by Georges de La Tour (1593–1652). The recent extensions of the city, especially since 1945, have taken place mainly in the south, beyond the railway lines and yards.

Rennes, which is the seat of an archbishop, is also the seat of a prefect (an *inspecteur général* supervising the whole region of Brittany), the headquarters of the 3rd Army corps, and the centre of a university (founded in Nantes in 1461 and transferred to Rennes in 1735) with faculties of law, arts, sciences and medicine. It is also the seat of a court of appeal and a court of assize. The town, a centre of communications, is an important railway junction on the Paris–Brest line, with lines to Saint-Malo and Nantes. The French railways have extensive workshops east of the town. Rennes is a nexus of roads and road transport, where two main axes meet, Paris–Brest and Saint-Malo–Bordeaux. The large airport of Rennes–Saint-Jacques was still partly under military control in the early 1960s.

Rennes, originally an agricultural centre, was before World War II a food-producing town with a few light industries. Postwar developments have led important industrial firms to establish themselves in the town, the main example being the large Citroën automobile works. Other factories include furniture, agricultural implements, chemicals, fertilizers and printing presses.

In Celtic times, Rennes was the capital of the Redones. The Romans made it the centre of communications of the province of Armorica. It was only in the 10th century, when the count of Rennes subdued the province, that the town became pre-eminent as the seat of the dukes of Brittany, and the place of their coronation. In 1356 Bertrand du Guesclin saved the town from capture by the English under the duke of Lancaster. The parliament of Brittany, founded in 1551, held its sessions at Rennes from 1561, they having been previously shared with Nantes. Henry IV entered the city in state in May 1598. In 1675 an insurrection broke out against tobacco and stamp duties. In the repression that followed parliament was transferred to Vannes where it remained until 1689. During the French Revolutionary Wars, Rennes at first opposed the decrees of the constituent assembly: then, reconciled with the revolution, it became the headquarters of the Republican army against the army of the Vendée. (C. F. L.)

RENNET, a milk-clotting preparation from calf stomachs, used in making junket, cheese and casein (*q.v.*).

If the fourth stomach (abomasum) of a calf is cut up and covered for several days with 10% brine and a preservative (*e.g.,* thymol), the extract so prepared will contain the enzyme rennin and will curdle many times its own volume of warm milk. This is a result of the action of the rennin upon one of the several kinds of casein present in the milk. A large fragment of the molecule is split off. Rennin is secreted by the gastric mucosa of the calf in the form of an inactive substance prorennin, which is changed into rennin by contact with dilute acid. Rennin, like pepsin, digests proteins but it differs from pepsin in requiring only a mildly acid reaction and in breaking fewer bonds in the protein molecule.

The clotting of milk does not necessarily indicate the presence of rennin since most, if not all, proteolytic enzymes including those from plants can clot milk. When sufficiently purified, rennin crystallizes as microscopic cubes, capable when re-dissolved of coagulating about 10,000,000 times their own weight of milk. (N. J. Be.)

RENNIE, JOHN (1761–1821), Scottish civil engineer, who built or improved many canals, bridges, docks and harbours, was born at Phantassie, East Lothian, June 7, 1761. He worked under Andrew Meikle, millwright, and attended classes at Edinburgh university, though he did not graduate. His first major work was the Albion mills, Blackfriars, London (built 1784–88, destroyed by fire 1791). Rennie greatly extended the use of iron for gears and other parts of machinery. After John Smeaton (*q.v.*) retired, Rennie carried out work on the Kennet and Avon, Rochdale, Lancaster and other canals.

From about 1800 Rennie carried out extensive drainage improvements in the Lincolnshire fens. He constructed or improved many harbours including Wick, Grimsby, Holyhead and Hull and built the London and East India docks on the Thames, and many bridges including Waterloo, Southwark and London bridges. He carried out extensive improvements to naval dockyards at Plymouth, Portsmouth, Chatham and Sheerness; he also began to build the breakwater that shelters Plymouth sound. Rennie died in London on Oct. 4, 1821, and was buried in St. Paul's cathedral.

After his death his business was divided between his sons. George, the elder, ran the mechanical engineering side and John (later Sir John) the civil, including the completion of London bridge and Plymouth breakwater.

See S. Smiles, *Lives of the Engineers* (1904). (S. B. Hn.)

RENO, a city of Nevada, U.S., the seat of Washoe county, is situated on the Truckee river, 14 mi. from the western boundary of the state, at an elevation of 4,500 ft. The city lies near the foot of the Sierra Nevada range amid magnificent and varied scenery. It has a moderate climate throughout the year.

Reno received its start in 1859 when a settler named M. C. Fuller built an inn on the south side of the Truckee river to accommodate travelers and freight teams from the Virginia City mines. When the Central Pacific railroad reached the spot in 1868, a land auction was held and homes were built almost overnight. The new town was named after Gen. Jesse Reno of Virginia, a federal officer in the American Civil War who was killed in the battle of South Mountain. Reno received a charter as an incorporated city in 1879.

Until 1900 Reno's business activity centred around its value as a distribution point. Then after several well-known people were granted divorces under the liberal state law, the town became famous as a divorce centre. (The state recognizes seven grounds for an absolute decree and requires only six weeks' residence before bringing suit.) Another attraction is the "no-waiting" period for marriages in Nevada. In an average year during the 1960s, for example, almost 20,000 marriages were performed in Washoe county compared with about 4,500 divorces granted.

Being close to the Sierra Nevada, Reno is a recreation centre during all seasons of the year. Good skiing, hunting and fishing areas are located nearby. With the full legalization of gambling in the state in 1931, the city began to attract tourists and weekend visitors to its many gambling casinos, most of which also furnish musical entertainment. The gambling combined with the fact that three federal highways run through the city account for the flourishing motel trade.

There are some small manufacturing plants in the area and Reno also continues to be an important warehousing and distribution centre because of Nevada's "Free Port" law under which merchandise originating in either the east or the west and moving in interstate commerce may be stored and assembled in transit free of taxation.

The University of Nevada is located on a beautiful 60-ac. campus overlooking the city from the north.

Immediately adjacent to Reno is the city of Sparks, founded in 1903 by the Southern Pacific Railroad company and named in honour of the state's incumbent governor at that time. For many years most of the town's residents were railroad employees. However, in the 1950s new housing developments constructed to meet the demands of people employed in Reno caused a sharp jump in population. The business district is centred along one main street which also serves as a federal highway. Gambling and the motel trade are also important businesses in Sparks.

The population of Reno in 1960 was 51,470. The Reno standard metropolitan statistical area, comprising all of Washoe county, had a population in 1960 of 84,743. For comparative population figures for both Reno and Sparks *see* table in Nevada: *Population.* (D. W. Ds.)

RENOIR, PIERRE AUGUSTE (1841–1919), French painter, one of the greatest of the Impressionists, was born at Limoges on Feb. 25, 1841, the son of a tailor who moved to Paris about 1845. After working as a painter of porcelain and as a painter of fans and banners, in 1862 Renoir entered the studio of C. G. Gleyre, where he made the acquaintance of Monet, Sisley and Bazille (with whom he frequently shared a studio until 1870). In 1864 and 1865 Renoir first exhibited at the Salon, but his entries were rejected in 1866 (despite the intervention of J. B. C. Corot and C. F. Daubigny) and again in 1867. With the closure of Gleyre's studio in 1864, Renoir spent some time of each year up to 1867 working in the region of Fontainebleau, frequently in the company of one or another of his friends. Although his studies in the Louvre had been devoted largely to the French painters of the 18th century, some landscapes of this period show the influence of the Barbizon school, while the influence of Courbet is more evident in the figure work (*e.g.*, "Diana," National gallery, Washington). In the years immediately following, Renoir worked in close contact with Monet both in Paris (1866–67) and at Bougival (1869), and the pictures executed (*e.g.*, "The Skaters," 1868; "La Grenouillère," 1869) represent one of the earliest stages of the concerns and techniques of Impressionism and were developed from the example set by Manet. The Salon of 1870 included, however, the "Bather," which is still reminiscent of Courbet, and the "Woman of Algiers," which gives clear evidence of Renoir's enthusiasm for Delacroix.

BY COURTESY OF THE PHILADELPHIA MUSEUM OF ART; TYSON COLLECTION

"BATHERS," (1884–87), BY PIERRE AUGUSTE RENOIR. IN THE C. S. TYSON COLLECTION, PHILADELPHIA MUSEUM OF ART

During the Franco-German War of 1870–71 Renoir served with a regiment of cavalry, returning to Paris during the period of the Commune in 1871. In the years immediately following, he resumed the practice of working with Monet, particularly at Argenteuil, near Paris. In these years (*c.* 1872–76) there developed, mainly by these two artists working in close collaboration, the form of painting known as Impressionism, a term usually understood to refer to a system of painting in which there is a far greater concern with the representation of light and atmosphere than with the representation of the physical characteristics of things and people. Renoir became a member of the "Société anonyme des artistes peintres, sculpteurs et graveurs," founded in 1874, and exhibited at four of the eight so-called "Impressionist" exhibitions organized by that society between 1874 and 1886. Characteristic examples of his work during the 1870s are "La Loge" ("The Box at the Theatre") 1874; "Portrait of Monet," 1875; "Paris Boulevards," 1875; "Mme. Charpentier and Her Daughters," 1878; and "Boating Party at Chatou," 1879.

During the course of 1881–82, Renoir visited Algeria, Guernsey and Italy (where he admired the work of Raphael and the wall paintings of Pompeii), and worked with Cézanne at L'Estaque. It was about this time that Renoir, in common with the majority of the Impressionists, began to modify his style. "I had gone to the end of Impressionism," he said later, "and I was coming to the conclusion that I did not know either how to paint or draw." The characteristic work of this period is the large "Bathers" (1884–87, C. S. Tyson collection, Philadelphia), which illustrates the renewed importance given to the representation of volume and structure defined principally by line, with colour (which tends to be acid) and brush strokes playing a subordinate role. A key work for the comparison of the style of the "dry period" with that of the preceding Impressionist phase is "The Umbrellas" (National gallery, London), which seems to have been painted over a number of years from about 1881–82 to 1885–86.

The work of the late 1880s is varied in character, but by the early 1890s the characteristics of the late style had begun to appear. In the late works the subject matter and the compositional devices of Impressionism are frequently used (*e.g.*, "Lunch at Berneval"), but the range of colour (usually based upon warm,

earthy reds and yellows) is arbitrary and personal and the paint is applied in a manner derived from the traditional system of glazing. The most frequent theme of the late years was that of the female nude characterized by a monumentality of proportions comparable to that found in Rubens, and by considerable stylization of features. Examples of this period are "Bather With a Hat" (*c.* 1904, Vienna); "Seated Bather" (1914, Chicago); "Woman Tying Her Shoe" (*c.* 1918, Courtauld Institute of Art, London) and "Rest After Bathing" (1919, Louvre, Paris).

In his late years Renoir undertook sculpture, but since he was crippled with arthritis almost all the works were executed by assistants working under close supervision. Renoir died at Cagnes in Provence on Dec. 17, 1919.

RENOUVIER, CHARLES BERNARD (1815–1903), French philosopher, leading exponent of the neocritical modification of Kantianism, was born at Montpellier, Jan. 1, 1815. He went to Paris in 1831 and attached himself at first to the comte de Saint-Simon and his group. He studied mathematics at the École Polytechnique (1834–36) and then devoted himself to the study of social science and philosophy.

Renouvier's first works were handbooks of philosophy, ancient (1842) and modern (1844); he contributed several articles to Pierre Leroux's *L'Encyclopédie nouvelle.* The revolution of February 1848 led him to write his *Manuel républicain de l'homme et du citoyen* (1848) and his *Gouvernement direct* (1851), the latter in collaboration with a group of democratic socialists. After the *coup d'état* of December 1851, he confined himself to philosophical and religious speculation.

Renouvier became the declared enemy of any doctrine that explained man's moral life in terms of a necessary though passing manifestation of a universal law or reality. His philosophical theories were related to three parallel themes. The first, derived from his study of Augustin Cauchy's work on the infinitesimal calculus, is the law of numbers: any real group must be finite. The second theme is liberty: free will is the root not only of moral life but also of intellectual life and no certainty is ever attainable without it. The third theme is idealistic relativism, derived from Kant and from Auguste Comte: only phenomena have any real existence and each phenomenon is relative in that it can only be apprehended as a component or a compound in relation to another given phenomenon. Renouvier claimed that all known systems of philosophy could be classified in one of two categories: (1) those maintaining the infinite, necessity, substance, the "thing in itself," historical fatalism, and pantheism; and (2) those maintaining the finite, liberty, phenomenalism, and theism. A choice had to be made between the two, but could not be determined on purely intellectual grounds. Renouvier's own option was determined by his belief that man has a moral destiny: a philosopher, he claimed, does not believe in death. He shared Leibniz' belief in the indissolubility of the monad. Thus Renouvier's universe is built around the destiny, not of humanity itself as with Comte, but of the individual. God, for him, is not a substance or an absolute, but the moral order itself, infinite only as the infinity of moral perfection.

Renouvier refused to believe in the inevitability of progress. His *Uchronie* (1876, anonymous; 2nd ed., 1901) gives an outline of the development of European society such as it might have been if Christian preaching had failed and Europe thus had had no Middle Ages. Later, his concept of the evolution of the physical world echoed Herbert Spencer's evolutionist naturalism. Renouvier died at Prades on Sept. 1, 1903.

His works include *Essais de critique générale,* four volumes (1854–64); *Science de la morale* (1869); *Esquisse d'une classification systématique des doctrines philosophiques,* two volumes (1885–86); *Philosophie analytique de l'histoire,* four volumes (1896–97); *La Nouvelle monadologie,* with L. Prat (1899); *Les Dilemmes de la métaphysique pure* (1900); *Le Personnalisme* (1903); and *Critique de la doctrine de Kant,* edited by L. Prat (1906).

RENT, in law, is a periodical payment due from a tenant for the use of land, buildings, or other property. It is usually payable in money but is sometimes paid in kind. If payable to the landlord, as under a lease, it is called rent service; if to any other person, it is called a rent charge. *See* FARM TENANCY; LANDLORD AND TENANT; LAND TENURE: ECONOMIC AND AGRARIAN ASPECTS.

As a term in economics, with which this article is mainly concerned, rent is differently defined. According to the British economist Alfred Marshall, rent is the income derived from the ownership of land and other free gifts of nature. He, and others after him, chose this definition for technical reasons, even though it is somewhat more restrictive than the meaning given the term in popular usage. Apart from renting land, it is of course possible to rent (in other words, to pay money for the temporary use of any property) houses, automobiles, television sets, and lawn mowers on the understanding that the rented item is to be returned to its owner in essentially the same physical condition.

The more restrictive use of the term became popular rather early among writers on economic matters. For the classical economists of the 18th and 19th centuries, society was divided into three groups: landlords, labourers, and businessmen (or the "moneyed classes"). This division reflected the socio-political structure of Great Britain at the time. The concern of economic theorists was to explain what determined the share of each class in the national product. The income received by landlords as owners of land was called rent.

It was observed that the demand for the product of land would make it profitable to extend cultivation to soils of lesser and lesser fertility, as long as the addition to the value of output would cover the costs of cultivation on the least fertile acreage cultivated. On land of greater fertility—intramarginal land—the costs of cultivation per unit of output would be below that price. This difference between cost and price could be appropriated by the owners of land, who benefited in this way from the fertility of the soil—a "free gift of nature."

Marginal land (the least fertile cultivated) earned no rent. Since, therefore, it was differences in fertility which brought about the surplus for landowners, the return to them was called differential rent. It was also observed, however, that rent emerged not only as cultivation was pushed to the "extensive margin"—to less fertile acreage—but also as it was pushed to the "intensive margin" through more intensive use of the more fertile land. As long as the additional cost of cultivation was less than the addition to the value of the product, it paid to apply more labour and capital to any given piece of land until the net value of the output of the last unit of labour and capital hired had fallen to the level of its incremental cost. The intensive margin would exist even if all land were of equal fertility, as long as land was in scarce supply. It can be called scarcity rent, therefore, to contrast it with differential rent.

However, since the return to any factor of production, not only to land, can be determined in the same way as scarcity rent, it was often asked why the return to land should be given a special name and special treatment. A justification was found in the fact that land, unlike other factors of production, cannot be reproduced. Its supply is fixed no matter what its price. Its supply price is effectively zero. By contrast, the supply of labour or capital is responsive to the price that is offered for it. With this in mind, rent was redefined as the return to any factor of production over and above its supply price.

With the supply price of land zero, the whole of its return is rent, so defined. The return to any other factor may also contain elements of rent, as long as the return stands above the next-most-lucrative employment open to the factor. For example, a singer's employment outside the opera may bring a great deal less than the opera actually pays. A large part of what the opera pays must therefore be called rent.

The opera singer's specific talent may be nonreproducible; like

land, it is a "free gift of nature." A particularly effective machine also, though its supply can be increased in time by productive effort, may for a period also earn a quasi rent, until supply has caught up with demand. Where its supply is artificially restricted by a monopoly, the quasi rent may in fact continue indefinitely. All monopoly profits, it has been argued, should therefore be classified as quasi rent. Once this point has been reached in the argument, there is perhaps no logical barrier to extending the meaning of rent to cover all property returns. After all, profits and interest can persist only as long as there is no glut of capital. The possibility of producing capital would presage such a glut, one that has been staved off only by new scarcities created by technical progress.

See FACTORS OF PRODUCTION; LAND; *see* also references under "Rent" in the Index. (H. O. S.)

RENTON, a city in King County, western Washington, U.S., on the south shore of Lake Washington, is located about 12 mi. SE of Seattle. It can be reached by deepwater vessels from Puget Sound via the Ballard Locks and Lake Washington.

A large airplane plant, devoted especially to the manufacture of jet transports, is located there. Lumber, shingles, steel and clay products, railroad freight and passenger cars, logging machinery, and stokers are also produced. Coal mines near Renton, exploited since the 1860s, played an important role in the history of the Pacific northwest. Truck and poultry farming are the chief agricultural activities of the area.

The city was named for William Renton, one of the founders of a coal-mining company, and was incorporated in 1901. For comparative population figures *see* table in WASHINGTON: *Population.* (R. E. BU.)

RENWICK, JAMES (1662–1688), Scottish covenanting leader, the last of the prominent covenanting martyrs, was born at Moniaive in Dumfriesshire, on Feb. 15, 1662, the son of a weaver, Andrew Renwick. Educated at Edinburgh University, he joined that section of the Covenanters known as the Cameronians about 1681 and soon became prominent among them. (*See* COVENANTERS; CAMERONIANS.) Afterward, at their direction, he studied theology at the University of Groningen and was ordained a minister in 1683. Returning to Scotland to take up the work for which he had been trained, he became one of the field preachers and was declared a rebel by the Privy Council. He was largely responsible for the "apologetical declaration" of 1684 by which he and his followers disowned the authority of Charles II; the Privy Council replied by ordering every one to abjure this declaration on pain of death. Unlike some of his associates, Renwick refused to join the rising under the earl of Argyll in 1685; and in 1687, when the declarations of indulgence allowed some liberty of worship to the Presbyterians, he and his followers, often called Renwickites, continued to hold meetings in the fields, which were still illegal. A reward was offered for his capture, and early in 1688 he was seized in Edinburgh. Tried and found guilty of disowning the royal authority and other offenses, he refused to apply for a pardon and was hanged on Feb. 17, 1688.

BIBLIOGRAPHY.—Renwick's life by Alexander Shields, *Biographia Presbyteriana* (1827); R. Wodrow, *History of the Sufferings of the Church of Scotland* (1839); W. H. Carslaw, *Life and Letters of James Renwick* (1893); A. Smellie, *Men of the Covenant* (1904). (X.; H. WA.)

REPARATIONS. In their customary meaning reparations are a levy on a defeated nation forcing it to pay some of the war costs of the winning countries. They were levied on the Central Powers after 1918 to compensate the Allies for some of their war costs; they were meant to replace war indemnities which had been levied after earlier wars as a punitive measure as well as to compensate for economic losses. The United Nations (UN) levied reparations after World War II, principally on Germany, Italy, Japan, and Finland. In the decade following the war, the meaning of the term became more inclusive; it was applied to the payments undertaken by the Federal Republic of Germany to the state of Israel for crimes against the Jews in territory controlled by the Hitler regime and to individuals in Germany and outside it to indemnify them for their persecution. The term was also applied to the obligations of Israel to the Arab refugees who suffered property losses after Israel's victory over the Arab states in 1948.

There are two practicable ways in which a defeated country can make reparation. It can pay over in cash or kind a portion of the goods and services it is currently producing; *i.e.*, a part of its national income. Or it can pay over in cash or kind some of its capital in the form of machines, tools, rolling stock, merchant shipping, and the like, which is a part of its national wealth. The payment of gold or other universal money is not a practicable method of paying reparations. The supposed consequence of reparations is a decrease in the income, and hence level of living, of the defeated nation, and an increase in the income of the victorious nation, the capitalized value of the increase being equal to its war costs. However, there is no warrant for these suppositions in either the economics of reparations or in historical experience with them.

Experience suggests that the smaller the reparations levy the more likely it is to be paid, and conversely that large levies are unlikely to be collected. In both World Wars I and II the failure to obtain desired reparations was unmistakable. Indeed, some of the victorious nations eventually had to make payments to the defeated in the interests of restoring economic and political stability.

Magnitude of Reparations.—The size of the defeated nation's liability cannot be determined by the war costs for which it is directly or indirectly responsible. These costs are of two kinds, economic and social. The economic cost of war is the value of civilian goods and services which must be forgone in order that resources can be used for war production, plus the capital destruction resulting from war. The social cost is the burden created by loss of life and disorder in social institutions. The loss of life has economic implications, but its cost cannot be measured because the labour value of human life is not capitalized as, for instance, the income value of equipment can be. Estimates can be made of the economic costs of war, and they are usually much in excess of the capacity of the defeated nation to make reparation. For example, after World War II the principal belligerents submitted claims of $320,000,000,000 against Germany. This sum was more than ten times the prewar national income of Germany (at constant prices) and an even greater multiple of income after the war.

Since the magnitude of reparations cannot be determined by war costs, it must be determined by the defeated nation's ability to pay, which is much less than its stated liability; and, surprisingly, the magnitude of reparations also is determined by the ability of the victorious nations to receive payments. Hence the size of reparations depends on three factors: (1) the national wealth or national income of the defeated nation; (2) the ability of either the occupying powers or the government of the defeated nation to organize the economy for the payment of reparations; and (3) the capacity of the victors to organize their economies for the productive use of reparation receipts. The first of these three factors is most important.

The political instability that usually follows a war makes it difficult to organize the defeated economy for the payment of reparations. Authority is diffuse and uncertain; there are conflicts among the victorious nations, and the populace of the defeated country is, to say the least, uncooperative, particularly in the matter of transferring its capital or income to recent enemies. Finally, the payment of reparations depends on the willingness and ability of the victorious countries to accept the new economic structure attendant upon transfers of income or capital. Here occurred the paradoxes of reparations history in the 20th century.

Following World War I, some of the Allied Powers were able to conceive of no limit to a justifiable tribute from Germany, but when payments out of income began, the Allies found the imports competing with domestically produced goods and services and thereupon took measures which prevented Germany from honouring its obligations. After World War II, the transfers of capital from Germany and Japan so threatened to dislocate the economic structure of Europe and Asia that measures were taken to reduce reparation liabilities.

METHODS OF PAYMENT

The payment of reparations in kind or cash out of income or capital constitutes an export surplus; *i.e.*, the paying nation sends out of the country more goods and services than it imports. Reparations are impossible without this surplus, and it is for practical purposes more dependent on increasing exports than on decreasing imports. The fact that reparations are possible only via an export surplus should not be obscured by the financial mechanics of reparations. The defeated nation usually compensates the private owners of capital for the export of the goods which constitute reparations, and to do this it taxes or borrows from its citizens. But reparations cannot be paid out of revenue raised internally; the revenue must be converted into income or capital for transfer to the victor nation or into the currency of that nation. After World War I, reparations were designed to be paid mainly in cash out of income. After World War II, they were meant to be paid in kind, mainly out of capital.

Payments in Kind.—If payments in kind are made out of capital, the defeated nation pays over to the victors specific assets within the defeated economy and titles to assets held abroad. After 1918, the Allies obtained the largest vessels in the German merchant marine and a small amount of additional capital. After 1945, the United Nations seized merchant vessels and industrial equipment in Germany and Japan, acquired German- and Japanese-owned assets within the victor countries and sought to obtain Axis-owned assets within neutral countries. Most of the owners of this property were compensated by revenue raised within the defeated nations, the effect being to distribute the burden of the loss among enemy nationals, whether property owners or not.

Reparations in the form of capital transfers in kind have certain, though limited, advantages. They avoid some of the more complex monetary problems of cash payments. They are adaptable to a general program of economic disarmament whereby victor nations dismantle and remove industrial equipment of actual or potential military value. Some of this equipment may be of immediate peacetime value to the victorious economies, relieving critical shortages and assisting in reconstruction. Against these advantages must be set the complex economic problems created by the transfers. It is difficult if not impossible to distinguish between industrial equipment of military value and that which can be used only to produce peacetime goods. The steel industry may be used for peaceful purposes or it may become the centre of the munitions industry. The war potential of an industry may be reduced by limiting its capacity but this also limits its peaceful uses. An even greater problem is the dislocation of economic structure which capital removals produce. Reducing plant capacity or eliminating it is a complex technical and economic undertaking. A slight error in removing too much of one kind of equipment can produce a great loss in another industry which in consequence must operate at undercapacity. Even with complete technical consistency in scaling down plant facilities there can be unnecessary losses when the reduced output is measured in monetary (*i.e.*, economic) units. The removal and transportation of capital is expensive, and if any of the labour is done by enemy nationals there is likelihood of additional expense through sabotage. Capital removals require a reallocation of resources in both the defeated and the victorious countries. During the process there is loss of income resulting from installation costs and partial unemployment. Meanwhile the defeated country may become a charge on its conquerors, requiring relief of various kinds until it can become self-supporting. These problems are present in the most ideal circumstances which can be supposed.

In the conditions likely to be present, capital reparations mean a long-term reduction in income for the victorious nations as well as for the defeated nation if, as is likely, the two trade with each other. This is probable because capital is removed from an economy where it has been used efficiently with trained labour to one where it must be used less efficiently for a considerable time. The net effect is then a lower income for all countries, victorious as well as defeated. This consequence is avoidable only by the creation of a perfect mechanism for the transfer of capital and by supposing that the recipient nations will be able to use it as efficiently as the paying nation. Such conditions are improbable. This being so, reparations are apt to produce quite the opposite of their intended effect. This was the experience after World War II.

Following World War I there was some payment of reparations in kind out of income. There were other instances of this method. Out of its annual production, a paying country exports certain commodities to its creditors or performs certain services for them. It can, for example, ship specified quantities of raw material, fuel, or manufactured goods, and it may perform transportation and labour services. It may send numbers of its workers to the victorious nation to restore areas damaged by the war and repatriate them when the work is completed. The difficulties encountered in a scheme of capital reparations are present here also but on a lesser scale. The excessive export of current output may force a reduction in plant operations within the defeated countries. The receipt of these goods and services by the victors disturbs their normal exchange pattern. After World War I, the immigration of German workers into France to restore the devastated areas caused French workers to protest that their wages were being reduced by the increased labour supply. After World War II, some British trade unions resisted the attempt of the Labour government to use German prisoners of war to relieve critical labour shortages. Similarly, some U.S. manufacturers complained that the import of Japanese goods on reparations account was driving down prices in the U.S.

Cash Payments.—Prior to World War II, reparations were more often made as cash payments than as transfers in kind. It was believed that such a method was easier to organize and more productive of a successful settlement (a viewpoint which was reversed after World War II). Cash payments can be made out of accumulated capital, in which case the paying country sells certain of its assets held either at home or abroad, converts the proceeds into the currency of the victorious nation and pays it over to the latter's government. The effect of capital transfers via cash payments need not be quite as disturbing as that of capital transfers in kind, though in practice both may produce much the same result. A conceivable advantage of the former is the greater opportunity given the paying nation to dispose of its capital at a minimum loss; it may sell it on the highest paying market and convert the receipts into the currency of the victor nation, while capital transfers in kind must be made directly to the victor nation and valued realistically at the worth to it.

After World War I, the bulk of reparations levied on Germany was to consist of cash payments out of income over a period of years. The successful execution of this plan called for an export surplus in the paying country and conversion of the surplus into the currency of the receiving nations. The effect was a reduction in the income of the paying nation and an increase in that of the recipients. Cash payments produce distinctive effects which are not present when reparation is made in kind; they arise because the debtor country must obtain the currency of the creditor nation. The nature and importance of the effects depend on the size of reparations in relation to the national income of the debtor and creditor countries, on the sensitivity of their price levels to expenditures and receipts from imports and exports, on the flexibility of their foreign exchange rates and on the money supply together with the rate at which it is spent. If any one result is more probable than others, it is a fall in the foreign value of the paying nation's currency and a concomitant rise in that of the receiving country. This in turn increases the real cost of reparations to the debtor and creates a corresponding gain to the creditor. Because its money buys less of the money of the creditor, the debtor must offer a greater quantity of exports in order to obtain a given quantity of the creditor's money. It is to be repeated that this is a probable, not an invariable, consequence.

There are two major conditions for the successful settlement of cash reparations. Payments must be within the defeated nation's ability to pay after full account is taken of their monetary effects, and payments must be acceptable to the receiving country. The latter must either increase its net imports from the paying nation or from a third nation which is in debt to the paying nation. The inherent complexities of a reparations program of

from his possession. The plaintiff, upon giving the sheriff security that he would both prosecute the suit and return the chattels if judgment was rendered against him, obtained immediate possession of the chattels until final judgment. The judgment awarded the chattels plus damages for their wrongful withholding. The action of detinue lay for chattels wrongfully detained by one who acquired possession rightfully. In the United States, statutes broadened replevin so that it lay to recover chattels wrongfully detained, whether or not wrongfully taken. *See* also PERSONAL PROPERTY. (E. M. M.)

REPNIN, ANIKITA IVANOVICH, PRINCE (1668–1726), Russian army officer, one of the collaborators of the emperor Peter the Great, grew up as Peter's playmate. He participated in the two Azov expeditions of 1695 and 1696 against the Turks and from 1700 to 1721 took an active part in many battles of the Northern War against Sweden. In the winter of 1705–06 he commanded the Russian Army besieged by Sweden in Grodno in Poland and in April 1706 succeeded in breaking through the Swedish lines and moving with his army to Brest. At the end of June 1708 he was ordered to hold Holowczyn (Golovchino) in Belorussia. The battle fought there in July was lost through the inadequacy of the precautions taken by Repnin and his tactical mistakes. As a punishment for his unworkmanlike and old-fashioned generalship Peter deprived him of his rank and his command. Reinstated in October 1708, Repnin distinguished himself at Poltava (1709) at the head of his infantry regiments. In 1724 he temporarily replaced Prince A. D. Menshikov as president of the War College. In the intrigues for the succession he first favoured Peter Alekseevich but after the emperor's death set an example to the other notables by joining the party of Catherine I (*q.v.*) and Menshikov, who rewarded him with the rank of field marshal. He died on July 14 (new style; 3, old style), 1726. (L. R. LR.)

REPNIN, NIKOLAI VASILIEVICH, PRINCE (1734–1801), Russian diplomat and general who won many victories over the Turks, was born on March 22 (new style; 11, old style), 1734, a grandson of Prince A. I. Repnin (*q.v.*). He joined the army and, after a period of study in Germany, was sent by the emperor Peter III as ambassador to Berlin (1762). In November 1763 Catherine II transferred him to Warsaw, with instructions to form a Russian party in Poland from among its Orthodox subjects (the so-called dissidents). Although the Polish *Sejm* (Diet) flatly refused to grant concessions to the dissidents, Repnin at first refrained from violent measures. Having failed to break the opposition of the Diet, however, he finally achieved Russian aims by force (October 1767).

In 1768, Repnin went to fight the Turks. At the head of an independent command in Moldavia and Walachia, he prevented a large Turkish army from crossing the Prut (1770); distinguished himself at the actions on the Larga and Kagul rivers; and captured Izmail and Kilia. In 1771 he received the supreme command in Walachia and routed the Turks at Bucharest. A quarrel with the commander in chief, Count P. A. Rumyantsev, then induced him to send in his resignation, but in 1774 he participated in the capture of Silistra and in the negotiations which led to the Peace of Kuchuk Kainarji. In 1775–76 he was ambassador at the Porte. On the outbreak of the War of the Bavarian Succession (1778) he led 30,000 men to Breslau, and at the subsequent Congress of Teschen, where he was Russian plenipotentiary, compelled Austria to make peace with Prussia (May 13, 1779). During the second Turkish war (1787–92) Repnin was, after A. V. Suvorov, the most successful of the Russian commanders. He defeated the Turks on the Salcha River, captured the whole camp of the *seraskier* ("commander in chief") Hassan Pasha, shut him up in Izmail, and was preparing to reduce the place when he was forbidden to do so by Prince G. A. Potemkin (1789). On the retirement of Potemkin in 1791, Repnin succeeded him as commander in chief, and immediately routed the grand vizier at Machin, a victory which compelled the Turks to accept the truce of Galati (Aug. 11 [N.S.], 1791). In 1794 he was made governor-general of the newly acquired Lithuanian provinces. The emperor Paul raised him to the rank of field marshal (1796), and, in 1798, sent him on a diplomatic mission to Berlin and Vienna in order to detach Prussia from France and unite both Austria and Prussia against the Directory. He was unsuccessful, and on his return was dismissed from the service. He died in Moscow on May 24 (N.S.; 12, O.S.), 1801. (Lo. L.)

REPOUSSÉ, in metalwork, the term used for designs raised in relief from the reverse side. *See* METALWORK, DECORATIVE.

REPRESENTATION, a term with the broad general connotation of making present something or somebody that is not present; but more especially the term is used in a political meaning and pertains to modern government as a method of solving the problem of how to enable a very large number of people to participate in the shaping of legislation and governmental policy.

Representation in the broadest sense has roots which link it with the world of beliefs called magic, a world in which mysterious connections were regularly assumed to prevail between distinct persons and beings, both natural and supernatural. Without going into the historical evolution of the various meanings of "represent," "representation" and "representative," it is worth noting that the modern governmental meaning was not attached to these expressions until the 16th century, when parliamentary development began. Sir Thomas Smith, in his *De Republica Anglorum* (1583), uses the expression freely in describing parliamentary institutions.

It must be admitted, however, that a magical element remained in spite of the continuous effort to rationalize the relationship spoken of as representation. Some writers, such as Jean Jacques Rousseau, simply denied that representation of the will of the people is possible. While few would be willing to follow Rousseau, it is generally agreed that representation of the electorate in modern representative assemblies poses very real problems, because the views both of the representative and of those represented are likely to undergo change as the situation changes.

Theoretical Problems of Representation.—In large modern countries the people cannot, of course, assemble in the market place as they did in democratic Athens or Rome. If, therefore, the people are to participate in government, they must select and elect a small number from among themselves to represent them and act for them. Through the course of a long historical evolution, the methods for such elections have been rationalized. The extended 19th-century struggle for electoral reform in England was fought over this issue; rotten boroughs, patrons and other features of aristocratic nepotism were eliminated. In these reforms, Jeremy Bentham's "rational" principle of utility prevailed against Edmund Burke's earlier defense of traditional practices. Direct general elections have since that time been accepted as the most "rational" method for choosing representatives, whether they be legislative or executive. For executives are also representatives of the people. The view that this is not so is a survival of attitudes developed during the monarchical age, when progressive forces fought the crown as unrepresentative. It is important that executives be included among the people's representatives because of the paramount role the executive establishment plays in modern government. Public policy in most modern democratic governments is shaped as much by the executive as by the legislative. Since parties are usually led by the chief executive, their role in determining the pattern of representation strengthens the executive's representative position.

Somewhat different are the role and position of the courts. The thorough legal knowledge required of a good judge has stood in the way of choosing judges by election. Wherever judicial bodies have been elective, much dissatisfaction has developed. In most jurisdictions, judges are ordinarily selected on the basis of technical competence—a relatively objective standard. Elections have not seemed a "rational" method. The supreme court of the United States would certainly seem to most people less representative if it were elected by the people. The reason for this is that all representation involves ideas; for only through an idea can the making present of one thing or person by another be conceived. Another problem would arise as the result of the divisions of the

electorate; minority interests might be neglected.

The deepest and most obscure aspect of representation is its ideological foundation. There has always been controversy between those who would have the representatives of the people act as delegates carrying out instructions and those who would have them be free agents acting in accordance with their best ability and understanding. The latter alternative was stated by Edmund Burke in his celebrated speech (1780) to the electors at Bristol:

> Parliament is not a *congress* of ambassadors from different and hostile interests, which interests each must maintain, as an agent and advocate, against other agents and advocates; but parliament is a *deliberative* assembly of *one* nation, with *one* interest, that of the whole; where not local purposes, not local prejudices ought to guide, but the general good. . . .
>
> Certainly, gentlemen, it ought to be the happiness and glory of a representative to live in the strictest union, the closest correspondence, and the most unreserved communication with his constituents. Their wishes ought to have great weight with him; their opinion high respect; their business unremitted attention. . . . But his unbiased opinion, his mature judgment, his enlightened conscience, he ought not to sacrifice to you, to any man, or to any set of men living. These he does not derive from your pleasure; no, nor from the law and the constitution. They are a trust from Providence, for the abuse of which he is deeply answerable.

Burke's idealistic conception accords neither with the reality of popular politics nor yet with the democratic ideal that the will of the people should prevail. The issue as to whose will is to prevail and is therefore to be taken as the will of the whole cannot be sidestepped by asserting, as Burke does, that parliament represents *one* nation, with *one* interest. While this is true in the abstract, the issue at hand is who is to say what that general interest is at a given time. For the conflict of various interests and their possible relation to a more comprehensive public interest is the real issue. Abstractly considered, a special mandate cannot be admitted, since it would make the members of representative assemblies into mandatories for special interests. But there is a great difference between a special mandate and a broad indication as to the general line of policy to be pursued.

The reason that the elected representatives of a party can be said to represent their electorate is basically that these representatives and those whom they represent are bound together by a world of ideas and beliefs that they share. Consequently, it can be assumed that any conclusion the representatives come to with regard to a new issue is likely to be the same as the conclusion the electorate would have come to had it been able to consider the new facts. But one gets lost in metaphysics of a rather shady sort when one claims that the majority represents the minority in any concrete sense. It is the majority and the minority together who represent the people as a whole and their general interest. But what about the single chief executive? All attempts to lift a chief executive above parties have proved abortive. A disastrous example is provided by the institution of the presidency under the German republican (Weimar) constitution. Such insistence upon the nonpartisan character of the chief executive is a result of the persistence of ideas prevalent during the monarchical age, when the king or the crown was supposed to be the preordained representative of all.

Dual Nature of Representation.—Historically speaking, representative assemblies developed in most European countries in the course of the later middle ages as an important part of the medieval constitutional order. Though great variations existed, the three estates were usually composed of nobility, clergy and the merchants of the cities (the burgesses). In the English parliament the higher nobility was joined with the higher clergy in "the lords spiritual and temporal," while the lower squirearchy and the burgesses together constituted the commons. This latter, the English system of two estates, proved more viable than the commoner continental system of three. The representatives of the lower estate were originally called by the crown in order to secure additional financial support over and above the feudal dues. (*See* FEUDALISM; PARLIAMENT.) Quite naturally, these representatives when gathered together proceeded to present complaints and petitions in an effort to strike a bargain. Such bargains were in favour of their own class. They represented their class as agents of the local powers and acted under instructions or mandates. But when, after the deal was struck, the king and the two houses of parliament acted together as "the king in parliament," they were taken to represent the whole realm. This historical background shows clearly that it is not justifiable to draw the sharp distinction Burke had in mind between agents with definite instructions and representatives speaking for one nation. An elected body is both: a deliberative assembly from *one* nation with *one* interest, that of the whole, *and* a congress of ambassadors from different and hostile interests. This dualism in political representation cannot be escaped. Many political philosophers have tried to do it, but with unsatisfactory results. The fascists and Communists have, by their insistence upon a monistic view, been forced into seeking some kind of religious or inspirational sanction, deifying the state, the proletariat or the folk and their respective leaders. The dualism of representing both the whole and one or another of its parts lies deeply embedded in representative schemes.

Representation Defined.—In the light of the foregoing, it is possible to suggest a definition of political representation: Representation is the process through which the attitudes, preferences, viewpoints and desires of the entire citizenry or a part of them are, with their expressed approval, shaped into governmental action on their behalf by a smaller number among them, with binding effect upon those represented.

Some features of this difficult definition require further comment. It is necessary to speak advisedly of attitudes, preferences, viewpoints and desires, rather than of will, influence or control, because the large citizen bodies of modern times do not possess a clearly defined will in most matters of public policy, because of lack of knowledge. It is necessary to use the general expression "governmental action," rather than legislation or policy, because all kinds of governmental activity are expressive of popular reactions. Perhaps the most important part of this definition is the phrase "with their expressed approval." Since such approval can be secured only periodically, it must be in a form covering a specified period of time. Finally, it is essential for genuinely representative action that it be accepted by those represented as theirs and hence binding upon them in all its consequences—a result which flows from their expressed approval. But while periodic elections are the commonest method for demonstrating expressed approval, there are exceptions, such as in constitutionally established courts, where the expressed approval may be found in a constitution adopted by common consent; or as in a special interest represented in so-called economic councils.

SOME HISTORICAL AND CONSTITUTIONAL ASPECTS OF REPRESENTATION

Representative systems of the rationalized type are a modern growth. They certainly were not found, as Montesquieu implied, in the forests of ancient Germany. It has been shown that political representation arose as part of the medieval constitutional order. Like so many medieval institutions, this political representation drew its inspiration from the church, whose vast body of the faithful was presumably represented by the great councils in which all Christian people were believed to be present.

Reasons for the Late Appearance of Representation.—But why did representation appear so late in the history of mankind? Essentially, the answer must be that it was not needed before modern times. The great empires of Asia had been animated by religious beliefs in which the individual human being counted for little and his personal preferences for less. In classical antiquity, with its city-states, the small number of citizens made personal participation possible. Aristotle deemed this participation so vital that he opposed altogether a political framework larger than the average city-state. Such personal participation became impossible whenever such a city-state expanded beyond the local unit. Attempts to solve the problem through federal organization foundered because of the lack of an ideological base upon which a representative scheme might have been evolved. The Romans undertook to embody the citizenry of each city of their Latin federation in the Roman citizenry by using various fictions, but the system broke down when republican Rome expanded and the Ro-

mans adopted the Asiatic technique of deifying an emperor. Still, the Roman constitution unquestionably contained elements of genuine representation. These elements were crippled, however, by the ascendancy of the unrepresentative senate. By contrast, the spirit of corporate solidarity in the medieval towns, shires, monasteries and cathedrals was sufficiently developed to make the group willing to participate in the larger community through group representatives. Unless such solidarity provides a common base of ideas, true representation cannot take place.

Representation and Constitutional Government.—Except in small communities, constitutional government is impossible without a system of representation. Constitutional government is government in which the use of power is restrained by a constitution which defines the functions of various power-holders. Restraint necessarily calls for dividing governmental power. Undivided power is unrestrained power.

From a historical standpoint, the need for securing responsibility in government is the central objective in all the various schemes of representation. This is true even of completely supernatural schemes, such as that by which a king is supposed to represent God on earth. For this notion may be the most powerful restraint upon the ruler and provide an impulse for him and his officials to act justly and avoid abuse of power. Examples abound not only in the experience of Europe but in such systems as the sultanate of Turkey or the empire of China. But this scheme works only as long as the faith lasts. If the ruler becomes an unbeliever, the most arbitrary tyranny easily develops.

The division of power may take many different forms. Perhaps the two most important modern forms are the so-called separation of powers, and federalism. For both, representation is of vital importance. Distinct federal divisions of the electorate, created and maintained under a constitution, require the selection of distinct groups of representatives among whom the several functions of government may be divided. (*See* FEDERAL GOVERNMENT.) The same is true under any kind of separation of powers; it presupposes a variety of representatives for different constituencies. Looked at from this angle, these schemes for dividing "power" really amount to dividing the people in a number of different ways and then giving these several subdivisions a voice in shaping governmental action through different representatives who are kept from abusing their power by holding each other in check. Such a plan could, of course, have no practical effect unless the community were actually divided into a number of groups, parties and classes.

Not only does constitutional government depend upon representation, but representation in turn depends upon constitutionalism. For unless the community is ready to agree upon and live by a basic charter in accordance with which power is wielded, plans for representation are liable to break down, as they did in post-World War I Italy and Germany. The representative quality rests upon a belief in common ground as far as doing things is concerned, and while there is no need for agreement on fundamentals other than the constitutional mores themselves, the latter, which have sometimes been called constitutional morality, are indeed of paramount importance. Representation, it might be said, is a game in which the rules are prescribed by the constitution as approved by the people. (*See* CONSTITUTION AND CONSTITUTIONAL LAW.)

Representation and Legislation.—Ever since the 16th century, legislation has been considered the most important phase of governmental action. Legislation involves the making of rules binding upon the whole community. Such general rules, it was felt, should bear the closest possible relation to the community's general beliefs. The higher law which Sir Edward Coke and others expounded as the yardstick for evaluating parliamentary statutes was believed immutable, a precious heritage of principles upon which all legislation should be based. At this point, the Protestant idea that one cannot force men in matters of belief, now generally accepted by all Christians as well as by many other faiths, reinforced the growing idea of the necessity of consent in matters of general legislation. A specific act of government may be justified in terms of a specific emergency, but no general rule can be considered valid unless assented to by those to whom it is to apply. Since the citizenry is too large, representation becomes essential. "No taxation without representation" is a vivid expression of this general view.

There is another aspect which suggests the use of representative assemblies as the natural agents for the purpose of making laws. A general rule presupposes that there is a series of events which have certain aspects in common. There must be a normal situation. If an event is recurrent, time elapses. Time is available, therefore, for deliberation to determine what is right and proper. Deliberative processes in turn are well suited to the relatively slow procedure of representative bodies. Nevertheless, the procedure of a well-organized representative assembly is so arranged as to result in action; namely, the adoption of a general rule. The enactment of such a general rule requires careful adjustment of conflicting viewpoints; really workable compromises need to be reached. Through argument and discussion the area of agreement is determined in the representative legislature. It symbolizes the consent which legislation presupposes, if it is to be compatible with the dignity of man's autonomy in matters of basic conviction and belief.

ELECTORAL SYSTEMS AND REPRESENTATION

In our discussion so far the electing of representatives has been spoken of as if an election were as simple a thing as throwing a stone. Actually, some of the most difficult problems of representation arise in connection with elections. Should elections be secret or public? Should limiting qualifications be required of those participating in the elections? How should the country be divided so as to make it possible for people to vote? These and related issues have all been sharply debated at one time or another, with a view to their bearing upon the central issue of making the results representative.

To the ancients, democracy meant that the whole citizenry met in the market place and decided all matters of common concern. To the modern world, democracy means that the whole citizenry regularly elects representatives, after having read about their platforms in the newspapers or listened to them in a meeting or over the radio or television. But there is a great difference between those elections in which the citizen is confronted by a clear-cut alternative between electing either A or B, and thereby supporting either party X or party Y, and elections in which he must choose among A, B, C, D, E, F and so forth and thus align himself with one of at least half a dozen parties, none of which has any chance of securing a majority.

The English and U.S. System.—The so-called two-party system has long been traditional in the United States and Great Britain. British parliamentary government rested for a long time upon a strictly traditional system of elections. It abounded with abuses of all kinds, such as rotten boroughs—unpopulated or depopulated areas which retained the right of representation in parliament. Through a series of reforms Britain eventually arrived, in 1884–85, at the single-member constituency, though the constituencies continued to lack uniformity of size and structure. Elections thereafter were decided in England by relative majority or plurality. This means that the candidate who secures the largest number of votes wins the seat. The balloting is secret, though before 1885 it was public, with much brawling and rioting. The British electoral system is thus clearly directed toward the goal of dividing each constituency, and thereby all of the United Kingdom, into two parts: the majority which is to govern and the minority which is to criticize. This situation may mean permanent minority status for a man who belongs to the wrong party in a particular constituency. As the English writer Walter Bagehot wrote in *The English Constitution* (1873), "I have myself had a vote for an agricultural county twenty years, and I am a Liberal; but two Tories have always been returned, and all my life will be returned."

The main criticism brought against this system of single-member constituencies is that the number of representatives elected is usually not proportional to the ratio of votes cast. Such is virtually certain to be the case, because in many constituencies one

of the parties may predominate, as Democrats do in the southern states of the United States or Tories do in many rural constituencies in England. It may result in apathy among the voters, or in a shift to primary contests as the key political decision. It may even happen that a minority of votes secures a majority of representatives.

Gerrymandering ("Electoral Geometry").—If the desirability of a majority (plurality) system of elections be conceded, the issue of how to divide the electorate appropriately is of great importance. As long as the population shifts, periodic readjustments of the boundaries of electoral districts are necessary, if gross injustices such as rotten boroughs are to be avoided. In the United States and elsewhere this issue is a familiar one; there is a recurrent political fight over reapportionment. Even with skillful and competent handling, there are bound to be lags. Under adverse conditions, reapportionment becomes a football of party politics. Since in order to gain a seat all a party needs is a small majority of votes, it is very tempting for the party in power to redraw the political map, that is, the boundaries of districts, wards and other subdivisions, so as to distribute its voting power most effectively. The resulting shapes of electoral subdivisions are often fantastic and not even always contiguous. Because a salamanderlike sprawling district was first constructed under a governor of Massachusetts, Elbridge Gerry, in 1812, this practice is known as gerrymandering. It is easy to construct cases which illustrate how the same electorate may give a majority to opposing parties as a result of adroit electoral geometry. (*See* APPORTIONMENT, LEGISLATIVE.)

The Issue of Proportional Representation.—The nonproportionality of single-member constituencies electing representatives by pluralities as well as gerrymandering has given rise to a series of proposals for proportional representation which seek to remedy these defects. The idea first appeared in the French national convention in 1793, without practical results. It was further elaborated by a number of writers (see *Bibliography*) who invented several systems.

It is clear that proportional representation responded to a widely felt need. The underlying idea of all the various proposals was to secure a representative assembly reflecting with more or less mathematical exactness the various divisions in the electorate. Why should such divisions be reflected? "The voice of minorities should be heard," is the answer.

The most penetrating philosophical argument in support of the general idea of proportional representation was set forth by John Stuart Mill. He called it "one of the very greatest improvements yet made in the theory and practice of government. . . . In the first place, it secures a representation, in proportion to numbers, of every division of the electoral body: not two great parties alone . . . but every minority in the nation. . . . Secondly, no elector would be nominally represented by someone whom he had not chosen. Every member of the House would be the representative of an unanimous constituency." Mill stressed the strong tie, the complete identification, the weakening of localism, the higher intellectual qualification of the representatives and the avoidance of collective mediocrity. Finally, Mill saw it as a check on "the ascendancy of the numerical majority" by offering "a social support for individual resistance. . . . a rallying point for opinions and interests which the ascendant public opinion views with disfavour." In his enthusiasm, Mill called proportional representation "personal representation" which offers a refuge to the "instructed elite." No objections of real weight could be seen by Mill, though in his usual deliberate manner he examined a few which he found wanting. Yet it is obvious that his whole argument rested upon certain unexplained major premises. His is an extreme individualist argument which he reinforces by the undemocratic preoccupation with the enlightened few who might be lost in the shuffle of the ignorant mass.

But the key assumption is that there can be no representation of the whole without a representation of each of the whole's parts. What actually is the primary function of a representative assembly? Is it to represent or is it to do something else? To put the question is to answer it. The primary function is to participate in governing. In order to be able to do that, a representative assembly needs a measure of cohesion. It cannot be, as we have seen, solely a congress of ambassadors from different and hostile interests. It must be able to reach decisions.

The elusive quality of Mill's approach is made evident by the opposing view of Walter Bagehot, another eminent writer on government and a 19th-century liberal like Mill, albeit more to the right. Bagehot, in rejecting proportional representation, put the following question: What will proportional representation do to the functioning of a parliament as we know it? Bagehot was a practical man, a banker, and his great achievement in this debate was to spell out what everyone knew in practice, namely, that the function of a parliament was twofold: (1) for the majority to support the cabinet in its conduct of the government; and (2) for the minority to criticize the actions of the government. This combination of action and criticism enables a parliament to represent the people as a whole.

Bagehot considered the basic difference between election by majority and proportional representation the fact that proportional representation makes the constituency voluntary—each voter individually is able to choose his own constituency. He votes as a voluntary member of a group which has no other tie. A constituency being the group or segment of voters that is entitled to send a member to parliament or congress, this is indeed the basic point, although the language of advocates of proportional representation often obscures it. To put Bagehot's point another way, all proportional schemes suggest saying to the electorate: If a certain number among you, say 10,000, can agree upon a candidate, that candidate shall be elected. The majority system, by contrast, is based upon this approach: A certain number among you shall constitute an electoral district, and the one for whom the largest number among you vote shall be considered elected. "Under the compulsory form of constituency the votes of the minorities are thrown away. . . . Again this plan gets rid of all our difficulties as to the size of constituencies. . . . Again the admirers of a great man could make a worthy constituency for him." But central party organizations would acquire an overweening influence. "The crisis of politics would be not the election of members, but the making of the constituency. . . . The result of this would be the return of party men mainly. . . . Upon this plan, in theory voluntary, you would get together a set of members bound hard and fast with party bands and fetters infinitely tighter than any members now. . . ." These are brief bits from a memorable passage in Bagehot's *The English Constitution* which anticipated with remarkable clairvoyance some of the troubles that arose when proportional-representation schemes were actually tried. His arguments do not, of course, exhaust the problem. They are focused upon the issues which arise when the cabinet governs with the support of the majority of a parliament. They fail to take into account the problems which appear when the divisions or cleavages among the electorate have gone so far that failure to represent them adequately would undermine the belief of the people in the justice of the constitution.

Theory and practice suggest that the truth lies somewhere between the lines of argument taken by Bagehot and Mill. There are situations, such as in multinational Switzerland, where proportional representation is probably to be preferred, but then parliamentary government should be discarded or at any rate considered very difficult of operation. There are others, such as in Great Britain, where the later evolution of parliamentary government, with its increasing emphasis on executive leadership, would seem to make a majority system advisable.

The Problem of Justice.—A broader philosophical issue which deserves special consideration is the justice of a representative system. Mill, in his plea for proportional representation, laid considerable stress upon this aspect. "There is a part," he wrote in *Considerations on Representative Government,* "whose fair and equal share of influence in the representation is withheld from them; contrary to all *just* government. . . . The injustice and violation of principle are not less flagrant because those who suffer by them are a minority. . . ." Mill considers this matter of justice to the minority so obvious that he proclaims representation

in proportion to numbers the first principle of democracy. What kind of justice and democracy is this? Let it be assumed for the moment that representation should be that of individuals and that it is unjust to a minority not to be "represented," or "represented adequately." If there were only one such minority, perhaps it would not be too bad, although the number of representatives who would criticize rather than help to decide would be increased. It would mean less action, rather than different action. If there were many such minorities, so that no group any longer had a majority, it might mean complete inaction for long periods. This situation arose toward the end of the Weimar republic and spelled its doom. It arose in France in the 1930s with disastrous effects, and again in the early 1950s. What then about justice for the majority? Is it not a question of competing claims? Why should the question of what is just to the minorities be given precedence over what is just to the majority? Admittedly, the majority wants some action. If such action is, through proportional representation, delayed or altogether prevented, what is the justice of that? Problems of justice are problems of adjustment between conflicting claims.

The election of representatives, therefore, always involves the paring down of some claims; justice can be achieved only through a careful balancing of these. Presumably the majority's claims are weightier than those of any minority. Representation is a broad thing: The majority participates through acting, the minority through discussion and criticism. Proportionalists fail to consider the possibility that there might not be any majority at all, in spite of the fact that the need for action, and hence the existence of a majority, may be paramount. A just government is above all a government which governs. No government which fails to do that can possibly be just.

Experience with Proportional Representation.—As contrasted with the time when Mill and Bagehot wrote, there is today a substantial body of experience with the workings of proportional representation. But the conclusions to be drawn from this experience divide the experts. On the one hand the enthusiasts for the proportional scheme contend that it is the only truly democratic method that at the same time solves the problem of gerrymandering and other forms of corruption.

On the other hand, there are scholars who have been inclined to blame proportional representation for the collapse of the Weimar republic, as well as the general tendency toward the anarchy of multiple parties and boss rule. A detailed analysis of the 20th-century experience of Belgium, the Netherlands, the Scandinavian kingdoms, Switzerland and Ireland, as well as local experience in the United States and in the British Commonwealth, makes it difficult for the detached observer to agree with either of these views. Leaving aside the rigid list system used in the German republic, and generally condemned, it would seem that all these countries achieved substantial stability and a great deal of social progress under proportional representation, whether combined with parliamentary government or not.

The systems differ from each other in many interesting details. In Belgium lists were used, but the voter could indicate personal preference for individual candidates; in the Netherlands the same was true, but there was also a national pool; in Norway and Sweden there were likewise lists in use, but the voter himself determined how the candidates on the lists were ranked. In Denmark a complicated plan of combining single-member constituencies with proportional representation by way of a transferable vote was employed. Switzerland made use of a list system which gave the voter extreme freedom in making up his list and an almost mathematical representation of views in the community was achieved; yet the resulting complex party structure in the representative assembly permitted effective action, because the Swiss did not use a parliamentary system of government. Finally, Ireland adopted the single transferable vote system long advocated by the British Proportional Representation society, with virtually every county an electoral district. A critical evaluation of the different systems may be looked for in the special works suggested in the bibliography below. Suffice it to say that these countries found proportional representation compatible with their governmental tasks and settled down to a general acceptance of it. The same might be said of quite a few U.S. municipalities.

The conclusion regarding proportional representation is not simple. It all depends upon the group and class structure of the community, the constitution and pattern of the government at large, the extent to which foreign policy is vital and imposes its requirements of integration and consistency. The fact that Switzerland did well under proportional representation does not prove that the United States might do well also.

Yet proportional representation does provide an opportunity for political self-expression to minorities which are already crystallized as politically self-conscious groups. If the representative assembly is capable of integrating these conflicting groups, either by foregoing the task of "supporting" the government, as in Switzerland, or by remaining content to co-operate with a monarchical head, as in the Scandinavian countries and the Netherlands, proportional representation may work better than a majority system. In many U.S. cities the city manager has provided a neutral balance wheel which enables a city council proportionally elected to function effectively. (*See* also PROPORTIONAL REPRESENTATION.)

In the last analysis, the problem of representation under modern conditions should be seen functionally in relation to the task assigned to the representatives. Legislation is one function, executive direction and leadership another, judicial and administrative determination something else again. Any system of representation, electoral or other, which works will be acceptable to the people at large and considered just; any system which fails to do so will be rejected or will become a fatal flaw which may bring on the collapse of the entire governmental system. For technical as the problems of representation may seem, they relate to the very core of modern popular government: Unless the people can be made present in their thought, their opinions and their will, democratic government becomes impossible.

See also references under "Representation" in the Index.

BIBLIOGRAPHY.—Besides the broad philosophical discussions and some continental legal studies, there are only rather partisan analyses. The broad treatments of comparative government contain general analyses. Here might be mentioned Carl J. Friedrich, *Constitutional Government and Democracy,* ch. xiv, xv and xx (1950), and Herman Finer, *Theory and Practice of Modern Government* (1932). Special treatments are to be found in G. H. Hallett and C. G. Hoag, *Proportional Representation—the Key to Democracy* (1937), and F. A. Hermens, *Europe Between Democracy and Anarchy* (1951). An important source is still the *Report of the Royal Commission Appointed to Enquire into Electoral Systems,* Cd. 5163, and its *Minutes of Evidence,* Cd. 5162 (1910); May McKisack, *Parliamentary Representation of the English Boroughs in the Middle Ages* (1932); James Hogan, *Election and Representation* (1945); W. Konopczynski, *Liberum Veto* (1918). For American parties, *see* V. O. Key, Jr., *Politics, Parties and Pressure Groups,* 4th ed. (1958). (C. J. FH.)

REPRIMAND, a public, formal, severe reproof or censure administered to a person at fault by his superior officer or by a body to which he belongs. The presiding officer of a legislature may reprimand a member for improper conduct in that body, in accordance with a vote of the house censuring him for a violation of its rules, such as disorderly conduct in the house or intemperate language in debate. A military officer may be punished by a reprimand administered by his superior officer or the civilian head of the military department, and in English law the most familiar use of the term is as a sentence imposed by a court-martial, as for example when a naval officer is found guilty of hazarding his ship but the court does not consider any more severe penalty is appropriate.

In ecclesiastical law, censure is a spiritual punishment which withdraws from a baptized person (lay or clerical) a privilege given him by the church, denies him the use of certain spiritual goods, or even expels him entirely from the church communion. One type of religious censure is inhibition, which is a command of a bishop or ecclesiastical judge, designed to compel obedience to his order or monition, that a clergyman shall cease performing any service of the church or other spiritual duty.

In civil law inhibition is a prohibition which the law makes or the judge ordains to an individual. Under Roman law, infamy was a censure on individuals pronounced by a competent state official; it resulted in disqualification for certain rights in public

and private law. Under the common law, conviction for an infamous crime disqualified an individual from giving legal testimony in court or serving as a juror. In modern times these disqualifications have largely been abolished by statute, so that a previous conviction affects the credibility of a witness but does not impair his legal capacity to give evidence. At common law, crimes resulting in infamy were treason, felony, or any offense such as forgery or perjury which involved deceit or falsification. Infamous crimes are now defined in terms of the punishment imposed—death or imprisonment in a state penitentiary. (RT. K.)

REPRISALS are measures of self-help in violation of normal international law to remedy past injuries or to stop continuing injuries in time either of peace or of war. They have been considered permissible only if in retaliation for an injury resulting from a violation of international law, if peaceful measures for obtaining redress have been exhausted without success and if the measures adopted are no more severe than the injuries complained of. (Naulilan Incident, Portugal and Germany, Arbitral Decision, July 31, 1928; H. W. Briggs, *The Law of Nations*, p. 951 [1952].)

Formerly a private person might be given "letters of marque and reprisal" by his government permitting him to seize ships of foreign flag at sea in order to gain compensation for a claim against a person of the nationality of the vessel's flag, in case the courts of that state had "denied justice." This practice was, however, ended by the Declaration of Paris (1856), which abolished privateering. Reprisals were, therefore, permitted only by the public forces of a state. (*See* PARIS, DECLARATION OF.)

Reprisals in time of war should be preceded by a public declaration calling upon the enemy to cease its illegal behaviour; should, so far as possible, be of a type not to injure innocent enemy or neutral persons; and should be stopped as soon as the enemy discontinues its illegal behaviour. The legitimacy of naval reprisals against the enemy, but injuring neutral commerce, was a matter of controversy between the United States and Great Britain before the War of 1812 and during the period of U.S. neutrality in World War I. In spite of neutral protest, British prize courts sustained orders in council, injurious to neutral commerce, in their character of measures of reprisal. (*The Fox*, Edw. 311; *The Stigstad*, [1919] A.C. 279; *The Leonora* [1919] A.C. 974.)

Reprisals in time of peace have taken the form of territorial occupation, administration of customs, detention of vessels in port, and "pacific blockade." The United States has contended that vessels of third states cannot be seized or otherwise interfered with for breach of "pacific blockade" although they can for breach of a "war blockade." In 1902 Germany, Great Britain, and Italy changed their pacific blockade of Venezuelan ports to a war blockade in response to a protest based on this contention. In the 19th century, pacific blockades in fact often extended to vessels of third states, and a League of Nations committee held that in accord with this practice economic sanctions against a covenant-breaking state might extend to vessels of nonmember states.

After the occupation of Corfu by Italy in 1923 as a measure of reprisal against Greece, a League of Nations committee of jurists implied that the obligation of members not to "resort to war" prohibited reprisals of warlike character. The more extensive obligations, of parties to the Kellogg Pact of 1929 and the United Nations Charter, to settle disputes only by peaceful means and to refrain from use of threat or force have been held to abolish peacetime reprisals in international law unless authorized by a competent international authority. Hostile acts in "individual or collective self-defence" against "armed attack" are, however, permitted by the charter (art. 51).

In August 1964 the United States executed retaliatory attacks on North Vietnam naval installations after U.S. naval vessels were attacked in the Gulf of Tonkin. Similar retaliatory action was taken in February 1965 after attacks on a U.S. barracks at Pleiku and on other points in South Vietnam.

REPRODUCTION, the process by which living organisms duplicate themselves. This function of animals and plants is regarded by biologists as the most fundamental characteristic of life. A distinction is commonly drawn between duplication of substance within a single individual or organism (growth) and duplication of the individual itself (reproduction); this distinction inevitably breaks down wherever there is any question of what constitutes an individual, as in colonial animals and in many plants. The distinction also loses its meaning when analysis is carried to microscopic or submicroscopic levels of living material. The present discussion will begin with reproduction as commonly observed in the individual organism, and will then proceed to smaller living units.

This article is divided into two main sections: *Essential Features* is primarily an introductory survey of the diverse ways in which organisms insure the continuity of their species; *Physiology of Reproduction* deals exclusively with animal reproduction, chiefly nonhuman. Human reproduction is treated in detail in a separate article, REPRODUCTIVE SYSTEM. The details of plant reproduction are given in PLANTS AND PLANT SCIENCE; ANGIOSPERMS; and GYMNOSPERMS. Biological aspects of sex, sex determination, and sex ratio are covered in SEX.

I. Essential Features
  A. Sexual Life History
    1. Human Cycle
    2. Animal and Plant Cycles
  B. Asexual Reproduction
    1. One-Celled Organisms
    2. Many-Celled Plants
    3. Many-Celled Animals
  C. Cellular Aspects
    1. Hereditary Mechanism
    2. Cellular Cycle in Animals
    3. Germ Plasm Concept
    4. Alternation of Generations in Plants
    5. Sex Among Lower Forms
  D. Subcellular Aspects
II. Physiology of Reproduction
  A. Production of Sex Cells
    1. Male
    2. Female
  B. Hormonal Control
    1. Generative System
    2. Secondary Sex Characteristics
    3. Puberty
  C. Production of Offspring
    1. Fertility
    2. Pregnancy

I. ESSENTIAL FEATURES

Centuries of observation and experiment, culminating in the celebrated researches of Louis Pasteur, served to establish that living organisms, within the scope of competent observation, come into being exclusively as products of other similar living organisms. This generalization is often referred to as biogenesis, or the genetic continuity of species. The nature of the process of inheritance (*see* GENETICS) has been elucidated by intensive research, mainly during the 20th century, based on the pioneering studies of Mendel. It must be emphasized that what is inherited by organisms from their parent or parents is a life history: a process that may be as uneventful as the increase in size of a single bacterium or protozoon after fission, or as complicated as the succession of different larval forms and metamorphoses in certain parasites, but always eventually culminating in a form resembling the parent.

A. SEXUAL LIFE HISTORY

The mode of reproduction of new individuals in the human species furnishes a sexual-biparental life cycle that may be taken as a norm for the animal kingdom, both vertebrate and invertebrate.

1. Human Cycle.—The general aspects of the human life history may be enumerated as follows. Adults are of two mating

types, or sexes: either male or female. Each mature adult contains within its body paired reproductive glands, testes or ovaries respectively, active usually on a cyclic basis. The reproductive glands produce germ cells, or gametes, sperm and egg cells respectively, which carry the hereditary pattern to the next generation.

The union of the germ cells from the two parents results in a zygote, or fertilized egg, which embarks on a series of relatively rapid progressive transformations. This period of rapid change is the portion of the life history with which the science of embryology is chiefly concerned. Briefly, the zygote divides by repeated cleavage, with little or no increase in the total mass of living material, until a hollow ball of cells (blastula) is formed. The fluid-filled blastula, or blastocyst as it is termed in mammals, passes into the uterus, or lower portion of the duct leading from the ovary to the exterior, but does not develop further unless implanted in the wall of the uterus or some equivalent site. This implantation is accomplished largely by the activity of the external cells of the blastocyst, which dissolve away the uterine lining locally. Meanwhile, the blastocyst enlarges and its internal portions undergo marked growth and cellular translocations involved in the process of gastrulation, which culminates in the production of a three-layered embryo enclosed within protective membranes. The peripheral extra-embryonic tissues, at this time, form an inextricable union with the maternal uterine wall, composing a temporary intermediary organ, the placenta, between maternal and embryonic body. Respiratory, nutritive, and excretory exchanges take place through the placenta.

The three embryonic or germ layers (ectoderm, mesoderm, entoderm), by processes of folding, local thickening, or budding, form the axis of the embryo within the protective membranes. This is, in general, a polar process, beginning at the anterior end and progressing posteriorly. During the first part of the life history of an individual, the anterior levels are always developmentally in advance of the posterior ones; the balance is not fully redressed until adult proportions are reached. The main features of the embryonic axis are first marked out: the neural tube, the notochord underlying it, and the mesodermal somites or segments lateral to these two median organs. The organ systems of the body arise by orderly local modifications of the primary germ layers.

The human body is complete as far as the organ rudiments are concerned by the sixth week after fertilization. From this time on, increase in size, in an orderly differential growth pattern, and physiological maturation of the several organs, are the major features of development. Approximately ten lunar months after fertilization, the new individual is capable of independent existence and is expelled by the maternal body. Then follow the developmental stages known as infancy, childhood, adolescence, etc., which are in effect a continuation of the intrauterine growth period at an ever-decreasing tempo. By the time the growth rate of the individual as a whole has decreased to zero (some tissues of the body never cease growing), the period of sexual maturity has been reached. The individual is now capable of being parent to a new generation, and the cycle is complete. After maturity, senescence and death complete the history of the separate individual.

2. Animal and Plant Cycles.—For an understanding of the sexual life-cycle as found in the plant and animal kingdoms, certain special aspects of the human model should be emphasized.

Parental Protection.—In man, as in practically all other mammals, the fertilized egg is retained within the female reproductive passages during the period when changes are most intensive and when, presumably, the new individual would be most susceptible to injury. In seed plants, the fertilized ovum is protected by the embryo sac, seed coverings, and ovary wall. In many animals the young are retained within the maternal body until they are fully motile and capable of getting food for themselves. In most of these cases the new individual has a preformed food supply in the yolk of the egg. There are instances, however, in which an organ of nutritive exchange (placenta in higher mammals) is formed between mother and embryo; but examples can be cited of similar organs from among cartilaginous fish, amphibians, even insects.

Physical protection may be furnished the new generation by the old in the form of external brood pouches (some degree of chemical interchange may occur even in this relatively external situation). Such devices are found particularly in certain specialized aquatic forms: the sea horse, certain crustaceans, echinoderms, etc. In other cases, parental protection takes the form of elaborate behaviour patterns involving cocoon production in earthworms, and nest building and guarding in birds and fishes. Instinctive activity of this nature is common among insects, where the digger wasps furnish a spectacular example of maternal provisioning, and the social insects afford equally striking instances of collective responsibility for the immature young.

Critical Stages.—A second noteworthy feature of the life history is the presence of what may be called critical stages. Among placental mammals the most obvious of these is the implantation period. The mammalian egg develops as far as the blastocyst stage as a free individual; until then it can be kept alive and progressing even in artificial nutrients. At this point, however, development ceases and does not resume until implantation. The occurrence of some similar developmental block, or dormant period, lasting until some threshold is passed, is a feature to be found in many life histories. Often such dormant periods assume relatively lengthy proportions, as is the case in seeds of higher plants, resting spores in some of the lower ones; insect diapause; or in parasite life histories where development is blocked until a suitable host is available.

Asexual Phases.—A third element in the direct biparental life history pattern is the interposition of an asexual phase. Occasionally, in humans, one (rarely, more) asexual reproduction is interposed in the sexual cycle; this is called true, or one-egg, twinning. In some mammals, as the armadillo, such asexual multiplication is a regular feature of the life history. Among the invertebrate phyla are many cases where the normal life history includes a stage of asexual reproduction, usually budding or fission, which in some forms constitutes the major means of replicating individuals. In certain invertebrate groups, *e.g.* tunicates and coelenterates, a regular alternation of generations between sexual and asexual reproduction has been established as the life history pattern. In multicellular plants alternation of generations is the rule (*see* below).

Larval Stages.—Among vertebrates, the amphibians in particular display a fourth variant of the life cycle. Here, typically, the development of the zygote is external and largely unprotected by the parent; the primary development leads to formation of a precociously independent larva (*e.g.*, the tadpole stage of frogs and toads), living as an aquatic organism and looking very different from the parents. Only after considerable feeding and growing does the larva undergo a radical metamorphosis into the adult.

This life history pattern, in which a larval stage, or more than one such stage, is interposed between egg and adult, is typical of many marine invertebrates. In these cases, parental protection is minimal or nonexistent. Vast numbers of germ cells are produced and zygotes that survive the vicissitudes of the open sea develop rapidly into minute larvae, which, after feeding and growing, metamorphose into the parental form.

Among the arthropods, which are characterized by the possession of a nongrowing exoskeleton that is periodically molted, the life history can be resolved into a series of growth stages (larval or nymphal), punctuated by molts. In the higher insects (beetles, flies, butterflies, bees, etc.), certain molts are accompanied by truly radical changes, as from an active larva (a wormlike caterpillar or grub) to a quiescent pupa, and from a pupa to a winged and sexually mature adult. (*See* METAMORPHOSIS.)

In the case of parasitic flatworms (flukes and tapeworms) there are many instances of a whole series of successive larval stages in the life history, each adjusted to a separate host or to a transfer from one host to another, and frequently including asexual division cycles during the sojourn in a host. There are examples of paedogenesis, in which a larval form becomes precociously sexually mature. Regardless of the number of stages, the cycle always comes round to an adult form like that of the original parents.

Hermaphroditism.—There are many instances, both in plants and animals, where organs of both sexes occur in the same individual. The so-called perfect flower produces both male and female

sex cells. In flatworms, hermaphroditism is the rule, as it is in the free-living segmented worms of freshwater and land habitat and in many mollusks. Cases can be cited from other phyla. Experimental analysis of sex differences has revealed that, among vertebrates as well as invertebrates, the gonad rudiments are, at the beginning of their development, potentially bisexual; thus hermaphroditism may be considered latent in all sexual organisms.

In most overtly hermaphroditic organisms, self-fertilization is prevented by mechanical obstruction, or, more commonly, by the difference in time of maturation of the reproductive organs, so that germ cells of only one of the sexes are liberated at any one time (usually the male precedes). In some snails and bivalve mollusks, only one type of gonad is present, the hermaphrodite gland, in the follicles of which first sperm, then eggs, are produced. The production of these two sex cells indeed may overlap, sperm and eggs developing in the same follicle. (*See* HERMAPHRODITE.)

Parthenogenesis.—Parthenogenesis, the variant of sexual reproduction in which the egg may become activated without intervention of a sperm, is found normally in various invertebrates. Rotifers and water fleas, in particular, reproduce parthenogenetically during summer or favourable seasons; they also produce "winter eggs," which require fertilization and then enter a resting phase that outlasts unfavourable conditions. Parthenogenesis differs markedly from any type of asexual reproduction, even though no fertilization occurs, in that it involves the production of an egg with all its hereditary material and cytoplasmic structure. *See* PARTHENOGENESIS.

B. Asexual Reproduction

1. One-Celled Organisms.—Unicellular organisms, in many of which sexual processes have never been reported, all reproduce by cell division exclusively. Sexual processes, when they occur in one-celled forms, do not strictly speaking increase the number of individuals. The primary function of fertilization in these cases is not reproduction per se, but the promotion of hereditary variation.

2. Many-Celled Plants.—In multicellular plants, asexual reproduction takes two quite different forms. One is the so-called asexual reproduction of the sporophyte generation, involving the production of spores that develop, without fertilization, into gametophyte plants. This aspect of reproduction in plants is part of a complicated sexual cycle; it is not strictly comparable to what is called asexual reproduction in animals. Plants, however, also have a strong tendency to reproduce vegetatively; these processes bear much more direct comparison to asexual reproduction in animals.

Vegetative reproduction in vascular plants (ferns, seed plants) —*i.e.*, formation of tubers, stolons, bulbs, runners, rhizomes, buds, and indeed all growth and branching of the plant axis—is traceable to meristems, or reserves of cells that have not taken on a specialized form or function, but instead have remained capable of continued cell division. The meristematic tips of stems and roots, and certain other localized reserves, may become the source of a new axis if properly stimulated. Meristems are an intrinsic part of the organization of the vascular plant body; thus relatively indefinite growth is a property of even the most highly differentiated plants. In nonvascular multicellular plants (mosses, liverworts), asexual reproduction is accomplished by localized growth centres (gemmae, etc.) in less highly differentiated tissue regions.

3. Many-Celled Animals.—Among multicellular animals, various types of asexual reproduction are common. The sessile colonial forms such as sponges, coelenterate polyps, bryozoans, and tunicates may undergo branching, stolon formation, or budding not unlike the pattern found in plants. The reserve cells that give rise to branches and buds are not localized in tissue groups as are the plant meristems, but in coelenterates, at least, they are mobile, continually being replaced. It is not known to what extent an animal cell that has assumed a specialized function in the body can revert to an undifferentiated state and partake in any sort of asexual reproduction; it is possible that in lower animals, cells other than the known reserve cells can lose their specializations and participate in forming a new individual.

Flatworms and annelids frequently reproduce by transverse fission. Regeneration in these forms, clearly parallel to asexual reproduction, definitely involves reserve cells called neoblasts, but other types of cells may also participate. When the animal is severed crosswise, whether by normal fission or by cutting, reserve cells are mobilized at the cut surface, and the missing portions of the axis are reconstituted by a new growth or blastema that develops at this surface. (*See* REGENERATION.)

Asexual reproduction in some invertebrate groups is associated with protective devices for withstanding adverse conditions. Gemmules and statoblasts, as examples, are groups of cells in a dormant state, formed presumably from reserve cells and covered with resistant capsular material. The reserves appear to be mobilized in response to critical environmental conditions; formation of these reproductive devices is usually accompanied by the death of the parent colony, much as annual plants die after dropping their seeds.

C. Cellular Aspects

Cytologists and embryologists in the last half of the 19th century established the cellular basis of reproduction by delicate and precise microscopic examination.

1. Hereditary Mechanism.—The chromosomes, stainable threadlike bodies in the nucleus, are constant in number, form, and molecular structure in the cells of an organism and in all members of a species (discounting mutations and a slight variation that may occur between sexes). In most animals and in plant sporophytes, the chromosome set is demonstrably double: in humans, 23 pairs of chromosomes is the accepted number. This double condition is called diploid. At ordinary cell division (mitosis) each single chromosome is seen to split longitudinally into two strands. At this time all the chromosomes become tightly coiled, short and thick; the nuclear membrane dissolves, the chromosomes arrange themselves midway between the poles of the spindle, a fibrous bipolar figure that appears in the cell at this time. The two daughter strands of each chromosome pass to opposite poles of this spindle; thus identical (except for genic changes) chromosome sets are consigned to each of the daughter nuclei. The cytoplasm of the cell is then divided in two, and cell division is complete.

Since all cells in an individual are descendants, through mitotic division, of one zygote, the chromosome set is constant within the organism. The maintenance of such a precise species pattern, passed intact from one generation to the next, is easily understood in organisms reproducing in asexual fashion since mitotic division is the basis of all asexual reproduction.

In sexual reproduction, the crucial event is fertilization. In this case, two cells, sperm and egg (or their equivalents), unite to form one zygote cell. The nucleus of each germ cell carries a single, or haploid, chromosome set (only one chromosome of each pair). The zygote therefore contains the diploid set. In the reproductive organs, the divisions that give rise to the haploid germ cells are characterized by a special type of nuclear behaviour termed meiosis.

The random segregation of members of each chromosome pair into separate germ cells, and the reconstitution of the pairs by fertilization, account for the phenomena of Mendelian heredity. Visible traits are determined by genes, units of submicroscopic size arranged in a fixed pattern along the length of a chromosome. When a strand splits into two, each gene is duplicated. Duplication of the genes at cell division is not always perfect; occasionally an imperfect or slightly altered copy, or mutation, arises. The altered copy will duplicate its imperfection from that time on. (*See* GENETICS; MUTATION.)

2. Cellular Cycle in Animals.—In multicellular animals that reproduce sexually, meiosis occurs only in the specialized germ cells in the gonad. Two meiotic divisions occur while these cells are being transformed into sperms or eggs, as the case may be. In the male gonad, or testis, the germ cells enlarge slightly preliminary to meiosis. The two meiotic divisions follow in rapid succession, and the four equal-sized daughter cells generally remain together as they transform into sperm. The nucleus con-

denses to form the sperm head; certain cytoplasmic elements transform into the remaining elements of the sperm body, and the residual cytoplasm is cast off. In many species the transformation of cells into sperm is accomplished with the aid of nurse cells. In mammals, including humans, the germ cells, after meiosis, become enclosed within the cytoplasm of such nurse cells until they are fully transformed into sperm.

In all but a few exceptional cases four functional sperm arise from one original germ cell of the testis. The same is never true of the egg. In the female gonad, or ovary, the immature germ cells undergo a prolonged growth period before entering into meiosis; in most animals adjacent cells play a prominent role in growth, as nurse cells or the equivalent. Meiosis is not initiated until the growth period is completed. In many species (perhaps most) the egg is released from the ovary and the fertilization process initiated before the meiotic divisions are brought to completion.

Meiosis in egg formation (oögenesis) differs from that in sperm formation (spermatogenesis), not in the essential matters of chromosome segregation but in the distribution of cytoplasm. First and second meiotic divisions each result in one giant cell, the egg itself, and one abortive cell, called a polar body, containing its full share of chromosomes, but only a tiny sheath of cytoplasm. The polar bodies formed at the first and second meiotic divisions soon degenerate, leaving only a haploid set in the nucleus of the egg itself. Meiosis in egg formation thus results in only one functional gamete from each original immature germ cell, along with three abortive polar bodies.

Fertilization is a physiological reaction of great specificity. It occurs with few exceptions only between two members of the same species, and is limited temporally to a short interval of maturity in the germ cells. There are many adaptations among animals for ensuring that ripe germ cells will be available to one another at time most favourable for fertilization. Synchronism of breeding activity, under hormonal or other chemical control, is one such mechanism; internal fertilization, the production of tremendous numbers of gametes in forms with external fertilization, the motility of sperm, and the controlling action of seminal fluids surrounding the sperm, are others. The crucial process of fertilization itself is, however, dependent on the cell surface in both sperm and egg, where antigenic reactions similar to agglutination effects occur. Substances presumably released by both germ cells act on the surface of the opposite cell type; following this, the sperm is gradually engulfed by the egg surface. The sperm head then swells into a form resembling the egg nucleus and sooner or later unites with the latter to form a fully diploid zygote nucleus. The egg, continuing its surface activity, proceeds to divide. In some species spindle elements used in this division are brought in by the sperm. (The occurrence of parthenogenesis, however, indicates that the egg is capable of producing a complete mitotic apparatus unaided.)

After fertilization, the mitotic process takes over, and the zygote, in successive cell divisions, becomes subdivided into cells of proportions standard for the species. These cells progressively become more and more differentiated, partly, at least, because each cell derived its cytoplasm from a different region of the original egg cytoplasm. The different cells then react with one another in the complicated pattern of events that comprise formation of the embryo.

3. Germ Plasm Concept.—The behaviour of the chromosomal material during the life cycle gave rise, in the 19th century, to the concept of the germ plasm as stated by August Weismann. The germ plasm can be conceived as a self-reproducing, potentially immortal, entity that persists intact through the generations, and gives rise, at each generation, to a soma or body, often thought of as a transient shell or vessel for the germ plasm. Weismann originally thought the determining factors of development and reproduction to lie exclusively in the nucleus. It has been necessary to modify this view in consideration of the important role that cytoplasmic factors have been shown to play in embryonic development.

At present the concept of the germ plasm, or rather the germ line, is properly a cellular concept. The cleaving zygote is compared to a colony of cells, all derived from the original zygote by successive mitoses. Identical nuclei thus populate differing cytoplasmic regions. One such specialized cytoplasmic region, when brought into contact with one of these nuclei, interacts in such fashion that the cell retains the properties of the whole organism and thus is destined to become a potentially immortal germ cell, whereas its sister cells take on partial functions as integumentary, nervous, secretory, etc., in fulfillment of their somatic role. In support of this view it can be cited that in many animal species the prospective germ cells are recognizable very early in development, long before a gonad is present, and can be seen to migrate into the reproductive organ after it is formed. Samuel Butler's aphorism that a hen is only an egg's way of making another egg sums up the germ-line point of view.

4. Alternation of Generations in Plants.—In all plants above the most primitive, the life cycle falls clearly into a pattern of alternation of generations. The gametophyte produces germ cells, or gametes: sperm in small capsules, or antheridia; eggs singly in archegonia. The fertilized egg develops into a sporophyte, differing from the gametophyte in appearance and producing spores in spore cases, or sporangia. Spores, which develop without fertilization into gametophytes, are, in many cases, of two sorts: microspores, which become male gametophytes; and megaspores, which become female gametophytes.

The evolutionary history of plants has clearly progressed from a state in which the gametophyte generation was the prominent one, and motile sperms requiring aquatic conditions were the rule, to the most recent situation in the seed plants, in which the visible plant is the sporophyte. In seed plants the gametophytes are very reduced in size and very short-lived. The male gametophyte is the pollen grain, in which the fertilizing elements are two nuclei borne in the outgrowing pollen tube. The female gametophyte is the embryo sac, concealed in the base of the pistil.

Examination of the chromosome content of the nucleus at various stages of the life cycle has shown that meiosis invariably takes place at the time of spore formation. Spore mother cells, borne on the diploid sporophyte, generally undergo two meiotic divisions, so that four haploid cells result. In cases where the product will be a megaspore, the meiotic divisions are modified in a manner reminiscent of the formation of the animal egg and its three polar bodies. The gametophyte, in consequence of meiosis, is haploid; the germ cells it produces are therefore haploid. Thus the alternation of generations in plants is an alternation between diploid and haploid generations. Comparable chromosomal changes in animals that exhibit alternation of sexual and asexual generations have not been described.

4. Sex Among Lower Forms.—As pointed out earlier, the origin of new individuals among single-celled animals and plants always depends on cell division; *i.e.*, binary or multiple fission. This mitotic process may be modified in various ways. In fungi, particularly, nuclear division frequently occurs independently of cytoplasmic division. In protozoans, the mitotic spindle usually develops inside the nucleus before the membrane dissolves. In bacteria, where a distinct nucleus is not detectable, the occurrence of anything resembling a mitotic spindle is doubtful.

Under certain conditions, many unicellular species form germ cells that undergo fusion, or fertilization. Some species, particularly among algae, form isogametes, two types of cells that are structurally indistinguishable but physiologically complementary. Among molds, the ends of strands or hyphae may fuse to form resting zygotes, or zygospores. Many algae and protozoa however form anisogametes, two types of germ cells, one large and relatively immobile, the other small and motile. In higher algae, sperms and eggs are found. In parasitic fungi and protozoa, elaborate life cycles may be found where asexual multiplication occurs in one host and fertilization in the alternate host. The wheat rust and the malarial parasite are examples.

Among one-celled animals, the ciliated protozoa exhibit a unique sexual cycle. These forms have two sorts of nuclei: a macronucleus, or somatic nucleus, which degenerates when sexual processes occur; and one or more micronuclei, which become active when the macronucleus degenerates. Conjugation occurs between animals of suitable complementary constitution. At this time the

micronuclei undergo a series of divisions that are in effect meiotic. Four daughter micronuclei are formed by the division of each original micronucleus; three of the four degenerate, much as do polar bodies in egg formation. The remaining micronucleus divides into a stationary and a migratory daughter. The migratory element from each conjugating animal crosses over to the partner, and once inside, fuses with the stationary nucleus there. This constitutes fertilization, and accomplishes the restoration of the diploid state and the introduction of new hereditary material. The conjugating animals then separate, and each undergoes a series of cell divisions, during which both macro- and micronuclei are reconstituted from the zygote nucleus. Inheritance in these animals follows exactly the course that would be anticipated from this nuclear behaviour.

D. Subcellular Aspects

Modern genetics and biochemistry have shown that the causal mechanisms of reproductive cycles lie in the intimate molecular structure of protoplasm, particularly in the chromosomes. These bodies have been shown to be composed of deoxyribonucleic acid (DNA) combined with proteins of relatively simple structure. Proposed models of DNA structure suggest that the chromosome is a highly polymerized complex with a core of nucleic acid in the form of a double helical coil. Each strand is conceived as acting as a template or pattern for a complementary helical coil, breaking away from its partner and unwinding, then assembling smaller units on its surface in an order fixed by its own structure. Thus exact duplication of chromosomal strands can be envisioned; this precision is extended to duplication of mutations in the original. Biochemical studies have verified that the synthesis of new DNA precedes the visible splitting of chromosomal strands in mitosis.

In the ciliated protozoa the nuclei themselves behave as germ cells, crossing from one cell partner to the other. Nucleic acid particles can behave similarly. Viruses evidently are composed largely if not entirely of nucleic acid and protein. Introduced into cells, viral particles interact in a variety of ways with the nucleic acid of the cell. Bacterial cells, for example, display a series of phenomena relating fertilization to virus infection. Transformation of inherited characters in bacterial strains can be performed by DNA alone. In the process known as transduction, a bacterial virus carries a foreign nucleoprotein particle into a bacterial cell, whereupon the foreign particle may alter the heredity of the host cell. In certain strains of bacteria temporary conjugation of bacterial cells and exchange of hereditary material has been observed. In all these cases the interpretation is that newly introduced DNA has altered the genetic mechanism of the bacterium.

A second type of nucleic acid, ribonucleic acid (RNA), is closely involved in protein synthesis in the cytoplasm of cells. Thus the nucleic acids are implicated not only in the continuing heredity of cells, but in the continuing reproduction of their specific proteins. Biochemists interested in the possible course of evolution of living systems believe that the appearance of self-duplicating molecules was a critical event in the history of the earth. In contrast to other types of synthetic mechanism in mixtures of organic compounds, self-duplication makes possible systems relatively stable yet plastic enough to undergo variation and evolution. The whole subject of reproduction in the contemporary organic world can be related convincingly to the peculiar molecular structure and behaviour of the nucleic acids. (D. Rk.)

II. PHYSIOLOGY OF REPRODUCTION

The large variety of forms within the animal kingdom gives rise to many variations in the processes of reproduction. In general the insects, after mating, lay fertilized eggs at a time of year, and in a place or under conditions most suitable for food supplies for their larvae, during which time the main body increments for the adult condition occur. In amphibians and fishes fertilization and development of the egg frequently occur outside the body, although in a few species the egg develops internally and birth takes place when it has developed far enough to be self-supporting. In many reptiles and in birds the fertilized eggs laid contain considerable quantities of nutrient material so that the young when hatched can lead an independent existence, although there is considerable variation in this respect. The pigeon, hatched in an early stage of development, needs to be fed from the crop gland of its mother, whereas the chick, except for warmth, is quite independent of its mother at hatching. In marsupials such as the kangaroo, the young, born at a very early stage of development, are transferred to the pouch where they obtain milk until they are able to live independently. In placental mammals, too, there is considerable variation between species in the stage of development at which the young are born: the guinea pig is in an advanced stage, fully haired, and can eat solid food at birth; the foal can follow its dam for long distances; rats and mice have to be kept warm in a nest and are dependent on the mother's milk supply for some time after birth.

While in the lower forms of life the individual animal may be bisexual, in the higher forms this is of rare occurrence, partial hermaphrodites occurring from time to time in pigs, goats, etc. In a heifer born twin to a bull calf the fetal cow's sex organs are masculinized in utero by fusion of the twin blood circulations. In birds the female always contains the rudiments of the other sex. The processes of reproduction described below are those that occur chiefly in mammals, some reference being made to birds.

A. Production of Sex Cells

1. Male.—The essential cells concerned in reproduction—the spermatozoa—are minute structures visible only under the microscope. The exact form varies with the species, but in the main each sperm consists of a head that contains the genes and a tail, which, by lashing movements, propels the sperm through the surrounding fluid.

Sperms are produced in the testis, an organ that contains long coiled tubes lined with sperm mother cells which after meiosis become sperms. (*See* Cell: *Cell Division: Meiosis.*) Sperms begin to be formed at the age of puberty; the number formed gradually increases to the prime of life and decreases in extreme old age. From the testis the sperms pass through small ducts to the epididymis, a coiled tube adjacent to the organ. They pass quickly through the first half of the epididymis and are stored in the end portion, where they mature (sperms taken directly from the testes are incapable of fertilization).

In mammals the two testes are contained in the scrotum, a sac outside the body cavity. In the fetus the paired testes are developed in the body cavity near the kidneys, a position in which they remain throughout life in the lower animals and birds. In most mammals, however, they pass down through canals in the groin and descend into the scrotum; if this descent does not happen, the individual remains sterile, as sperm production (but not the other functions of the testes; *see* below) is prevented by the higher temperatures that exist in the body cavity as compared with the scrotum. If in the ram, for example, the scrotum is enclosed in insulating material the temperature is raised and he becomes sterile in a few days; after the material is removed, fertility returns again in a month or so. There are species differences in the degree to which the scrotum is held near or away from the body and hence differences in optimum temperature for sperm production and storage. The temperature at which the sperms are formed bears a relation to their length of life in the female tract, which is of course at internal body temperature. In the bull the scrotum is very pendulous, and the sperms live in the female tract only about 30 hr.; in the stallion, on the other hand, the scrotum is held closely against the body wall, and the sperms will live about 5 days in the female tract. In birds, where the sperms are produced from testes in the body cavity, they will live in the female tract for a considerable time; in the female turkey eggs can be fertilized for up to 30 days after a single mating. In the epididymis the sperms remain fertile for a period of about 30 days but retain their motility for a longer period. Under most circumstances the power of fertility is lost before that of motility.

At mating the muscular walls of the lower epididymis contract and force the sperms along the duct (vas deferens) toward the exterior. The number of sperms driven up in this way varies with the species but in all cases of normal fertility amounts to many

millions. Sperm numbers at an emission can be increased by "teasing" the male before service; this causes the epididymis to contract, forcing sperms into the lower part of the vas deferens from which they are ejaculated at mating. When, at mating, the sperms pass up the vas deferens, they are diluted with fluids produced by the accessory glands (the seminal vesicles, prostate gland, and Cowper's gland). These secretions provide a medium in which the sperms can swim; some of these secretions precede the sperm and lubricate the urethra, the common tube for both semen and urine, extending from the bladder to the penis. In some species, *e.g.,* rats, mice, and pigs, a jellylike substance prevents the sperm running out of the female tract.

For purposes of mating, the penis is rendered turgid by contraction of muscles over the veins so that the blood spaces within the organ become engorged with blood; failure of these muscles to function, for which there are various reasons, is sometimes a cause of impotency. During mating the sperms are deposited in the female tract (*see* below), but the exact position varies in different species. In the horse sperms are ejected through the cervix directly into the uterus; in cattle and sheep they are sprayed over the entrance to the cervix. Which of the two methods occurs in a species is determined by the form of the penis and of the cervix.

2. Female.—The essential cells in the female are the ova, or eggs. These are formed in the ovaries, which lie in the body cavity just below the kidneys. In mammals there is one ovary on each side, but in birds only the ovary on the left side is functional. Unlike the sperms, which are produced throughout adult life, the ova are preformed in the ovary before birth; in the newborn calf some 75,000 are present. The ova, which are microscopic in size, are nourished by surrounding cells that, as the ova ripen, increase in number and later produce a fluid that forms a vesicle, the Graafian follicle; as this fluid accumulates the follicle gradually rises and projects above the surface of the ovary. At the appropriate stimulus (see *Hormonal Control* below) the follicle ruptures and discharges the fluid and ovum into the top of the Fallopian tube, where, if mating has occurred, the egg is penetrated by a sperm and fertilization takes place. It is only in this position that fertilization can occur, so that the time during which the ovum can be fertilized is comparatively short, a matter of hours. The sperms do not attain their fertilizing power until they have been in the female tract for some hours, so that for fertility, mating should take place several hours before the eggs are shed. In most species the ovum requires about three days to pass down the thin Fallopian tube and gain entrance to the uterus, where it becomes attached and develops into an embryo. If fertilization does not occur, the egg perishes.

After the egg is shed from the ovary, the cells of the follicle, which have hitherto been nourishing the egg, enlarge and fill the space formerly occupied by the fluid that surrounded the egg. This transformed follicle is the corpus luteum, or yellow body, within the ovary, the function of which is to supply progesterone, a hormone that prepares the uterine lining for the reception of the developing egg. If the animal becomes pregnant, the corpus luteum persists for the whole, or in a few species (mare, woman) the early part of pregnancy only. If the animal is not pregnant, the corpus luteum disintegrates after a time that varies with the species (woman 14 days, cow 20 days, ewe 15 days).

The presence of an active corpus luteum in the ovary suspends the development of the remaining follicles, but development resumes as soon as the corpus luteum begins to die. Thus a cycle, the estrous cycle, is instituted in the ovaries and affects other organs of the female reproductive tract. The ripening of the follicle is associated with the period of estrus, or heat, the only time in most mammals that the female will accept the male. Estrus is followed by a quiescent period during which the corpus luteum takes control; when this body dies another estrous period begins. In women the menstrual period marks the atrophy of the corpus luteum; the uterine bleeding normally results from a withdrawal of progesterone and the consequent breakdown of tissues that were built up under the influence of the corpus luteum. Shedding of the egg occurs about 14 days after the beginning of menstruation (*q.v.*).

The changes that take place in the inner layer of the uterus during the estrous cycle bear a relation to the type of placenta that occurs in the species. In all species the uterine glands are modified under the influence of the corpus luteum (see *Pregnancy* below).

B. Hormonal Control

1. Generative System.—The functioning of the reproductive organs is controlled by hormones (chemical substances circulating in the bloodstream). The primary centre for the production of these hormones is the pituitary gland, at the base of the brain. Its close association with the nervous system (hypothalamus of the brain) is the means by which environmental conditions such as daylight hours (*see* below) can affect reproduction. The pituitary gland consists of two lobes, posterior and anterior. The former produces oxytocin, which is released into the bloodstream when the nipples are sucked; oxytocin causes contraction of the muscle cells surrounding the milk-producing cells, thus forcing the milk down into the teat. Similarly coitus or insemination stimulates a release of oxytocin, which, in this case, causes rhythmic contractions of the muscles of the female reproductive tract and drives the sperms upward to the tops of the Fallopian tubes. The anterior pituitary produces a number of hormones, among which are the three main reproductive ones: prolactin, which promotes milk secretion; follicle-stimulating hormone (FSH), which causes the follicles in the ovary to ripen; and luteinizing hormone (LH), which causes the follicles to rupture and form corpora lutea. The developing follicle generates estrogens, which give rise to the symptoms of heat, and prepare the female tract for the reception of sperm; the corpus luteum produces progesterone, which prepares the uterus for pregnancy and causes the mucus formed in the cervix (neck) of the uterus to become viscous, and so seal off the embryo from the exterior. To an extent that varies greatly from species to species, the placenta may assume the function of the ovary, and secrete both estrogens and progesterone. In some species the placenta also produces hormones of the pituitary type: in the first third of the mare's pregnancy a follicle-stimulating hormone (PMS, which stands for pregnant mare's serum, from which the hormone was first derived); in the human placenta LH activity is generated (which forms the basis for various pregnancy tests). Some placentas produce prolactin activity and so are concerned in some degree with the development of the mammary glands for milk production.

In most species the release of LH from the anterior pituitary is automatic; *i.e.,* after a sufficient buildup of estrogen by the ripening follicle. In a few species (notably rabbit and ferret) the release of LH does not occur without the additional stimulus of mating: at orgasm, the sensory nerves to the hypothalamus are stimulated, causing the release of LH. In some birds, such as the pigeon, this nerve stimulation can also be effected by "social stimuli." A female pigeon in solitary confinement does not shed its eggs, but if it can see other pigeons, or even itself in a mirror, eggs are shed.

When the end products of hormone action, or their synthetic counterparts, build up in the body, they dam further release of the primary hormones. Thus when tablets of stilbestrol (a synthetic estrogen) are implanted under the skin (as they are sometimes, to induce a sterile heifer to produce milk), the high concentration in the blood dams the secretion of FSH in the anterior pituitary; as a consequence the ovaries cease to function.

In the male the primary anterior pituitary hormones are necessary for the nutrition of the testes and production of the sperm. These primary hormones act on the interstitial cells of the testes (cells that lie between the tubules) inducing them to secrete secondary hormones (androgens), which in turn cause the development and formation of the secretions of the accessory male glands (seminal vesicles, prostate) and create the desire for, and power of, mating (sex drive).

2. Secondary Sex Characteristics.—The differences in plumage in birds, distribution of hair in man, and body conformation in cattle are the results of the action of secondary sex hormones on the parts concerned. If the testes and ovaries are removed from chicks at hatching, the adult plumage of each assumes the same

neutral form. When, however, the castrated male hatchling chick is implanted with an ovary, the adult plumage is completely female; when the spayed female hatchling chick is implanted with a testis, it assumes male plumage. However, body size does not change perceptibly. Among most mammals and birds the male is larger than the female. The cock that has assumed female plumage by transplantation of ovaries remains larger in size than the hen that has assumed male plumage by the transplantation of testes. Sex differences in body size are due mainly to size-controlling genes associated with sex and only secondarily to hormones.

The secondary sexual characters begin to develop in the young animal somewhat before the time at which fertility begins. These changes can be speeded up by the injection of anterior pituitary hormones: newly hatched male chicks thus inoculated for about 12 days develop enormously enlarged combs and wattles, utter squeaky crowing sounds, and attempt to mount their young hen mates. Similar changes can be brought about by injection of the secondary male hormones.

3. Puberty.—In the young animal the reproductive organs grow at much the same rate as the body as a whole, but at the age of puberty, when the reproductive hormones come into play, the sexual organs develop at a much faster rate than the rest of the body. Rearing poultry on a high plane of nutrition lowers the age at which the first egg is laid but not to the same extent as it increases body weight, for birds on a low plane of nutrition lay their first eggs at lower body weights than those on a high plane. This is also true for reproduction in cattle and mammals generally.

In young bulls high-plane nutrition speeds up sperm production but not to the same extent as it speeds up the internal secretions of the testes. On the other hand injections of FSH in young rabbits and calves will cause the shedding of the eggs long before the normal age of puberty and before the rest of the reproductive tract has developed sufficiently to support a pregnancy. These eggs, however, can be fertilized, and if transplanted to adults (*see* below), can develop into normal young.

C. Production of Offspring

1. Fertility.—*Female.*—This is controlled at three main stages in the process of reproduction: (1) the number of eggs shed; (2) the number of such eggs fertilized; and (3) the number of fertilized eggs that develop normally to birth.

(1) The number of eggs shed depends on the level of FSH in the bloodstream. Normally, a rabbit will shed about five eggs from each ovary, but if one or even one and a half ovaries are removed, ten eggs are still shed, showing that the number shed does not depend on the number of eggs in the ovary but on some substances (FSH) circulating in the bloodstream. In the cow and ewe, which normally produce one or two eggs, injection of PMS four days before the expected heat period will cause, according to dose, up to 30 or more eggs to be shed. Appropriate doses increase the percentage of cows and ewes producing twins. Fertilized eggs can also be taken from the tubes of one female and put into the tubes or uterus of other females at a similar stage of the estrous cycle. Such eggs can be kept alive for about three days outside the body; fertilized rabbit eggs have been sent successfully by air across the Atlantic. This method can also be used to increase the number of offspring of a female of good genetic worth: the animal becomes, in a sense, an egg-producing "machine," relieved of the burdens of bearing the young.

The number of eggs shed at each estrus is an inherited character and can be modified by nutrition and selection. Since the number of eggs shed is controlled by environmental and nutritional conditions as well as by genetics, selection for high fertility in sheep is best made by using rams from ewes that have a high lifetime average for high fertility. In young females the level of FSH in the blood is lower than in adult life so that in ewes the average number of eggs shed gradually rises to a maximum at about the fourth year.

Among many animals eggs are produced only during a specific breeding season. In some mammals (mare, cow, ewe, sow) the estrous phase may recur at rhythmic intervals during the year or during one limited breeding season; in others, like the bitch, one estrous cycle occurs in the season. The former condition is described as polyestrous, the latter as monestrous, the quiescence between the seasons being known as the anestrum. This system probably evolved in association with the most favourable time of year for their survival, which is usually the spring. The breeding season is therefore more limited in those breeds and species that have their origin near the poles. The mechanism that determines this cycle is based on the changing ratio of daylight to darkness hours throughout the year; this ratio, or photoperiod, acts on nerves in the region of the head to stimulate or inhibit the release of FSH from the anterior pituitary gland. In species that have a short gestation period (ferret, 6 weeks), or a very long one (mare, 11 months) *lengthening* daylight hours stimulate FSH release. In species that have a medium duration of pregnancy (ewe, 5 months), release is stimulated by *shortening* daylight hours. In both cases the animals are born in the spring. Under the influence of daylight hours the release of FSH gradually rises to a peak, then falls again toward the end of the breeding season. Thus, fewer eggs are shed very early in the breeding season than at its peak, which in sheep is some six weeks after the beginning of the season. In hens the winter production of eggs can be much increased by providing artificial light, turning a short day into a long one.

The shedding of the egg is sometimes prevented by internal factors. In the mare, where LH is normally in short supply, there may not be enough to rupture the follicle. In the cow, where LH is usually abundant, persistence of the corpus luteum and consequent prevention of ovulation is not infrequent. In woman, failure of ovulation (the menopause [*q.v.*]) occurs much earlier in the span of life than in other animals.

(2) The number of eggs fertilized depends very largely on the time of mating in relation to the time the egg is shed, for, as already mentioned, both egg and sperm have a short life in the female tract. In most species the times of estrus and ovulation are well synchronized, but in the mare and sow, where ovulation occurs before the end of a prolonged estrus, or in woman, where there is no estrus, the time relations are very important. Failure of fertilization also occurs where sperm production by the male is poor (*see* below).

(3) The number of fertilized eggs that develop normally up to the time of birth is influenced by many factors. In addition to diseases that cause abortion or absorption in utero of the young, there are genetic causes of malformation or death of the embryo. The most frequent cause is, however, probably due to deficiencies in the uterine secretions, which cause early death of the fertilized egg (see *Pregnancy* below).

Male.—Except in most birds and a few mammals such as the hibernating hedgehog, the nonbreeding season for the male is not so marked as for the female, although in all species with a nonbreeding season, sperm production is at a much lower level at this time. The male breeding season, when it occurs, is called the rutting season.

There are various causes of poor sperm production in males. Fevers temporarily reduce sperm numbers. There may be genetic causes and in some cases deformed sperms are produced. Blockage of the epididymis may also prevent the emission of sperms. The number of sperms produced by the male cannot be increased above the normal level by hormone injections and when one testis is removed only half the normal number of sperms are produced. Normal males produce many more sperm than are actually required for fertilization. By collecting such sperm and using it to artificially inseminate females, it is possible to increase the number of offspring produced by a male. Bulls of good genetic worth, which normally would produce only about 50 calves a year, may now father 10,000 calves a year. Under proper conditions bull sperms have been kept fertile for many years (*see* Fertilization).

2. Pregnancy.—During the early stages of pregnancy (*q.v.*) the uterine glands, under the influence of progesterone from the corpus luteum, secrete actively and prepare the uterus to receive the developing embryo. Progesterone initiates formation of the maternal part of the placenta, which is the means of transference of materials between mother and fetus. Oxygen and food pass from the mother's bloodstream to the fetal bloodstream, and waste

products flow in the opposite direction, from the fetus to the mother. Blood vessels in the cord attached to the navel of the fetus carry these products between fetus and placenta. During pregnancy the uterus enlarges greatly and its muscles become strong enough to expel the fetus at birth. In the early stages the uterus is expanded by the production of fluids within the fetal membranes. This fluid environment provides space within which the fetus can develop well cushioned from the mother's movements.

There are three main stages of pregnancy, each marked by a different method of fetal nutrition. In the first, the blastocyst stage, the developing egg, lying free in the uterine cavity, is nourished from the secretions of the uterine glands. A number of fertilized eggs in all species perish at this critical stage.

In the second, or embryonic stage, the embryo, after attachment to the uterine wall, is nourished by the outer (trophoblastic) cells of the membranes, which actively absorb nourishment from the maternal tissues. These cells have priority of nourishment, so the level of the mother's nutrition has little effect on the size of the offspring at this stage. During this time the placenta increases in size; the extent to which this occurs determines the amount of nutrition the fetus will receive in the third stage. In the case of twins each placenta will be smaller than that of a single one and in large breeds the uterus and placenta will be larger than in small breeds.

In the third, or the fetal stage, the placenta ceases to grow and the trophoblast cells atrophy; nutrition is supplied at this time by diffusion between maternal and fetal bloodstreams. During this time the level of nutrition of the mother is of great importance, particularly in the case of twins or triplets, where placental area is limited. This stage in cattle and sheep comprises the last 6 to 8 weeks of pregnancy; during this period the weights of the individual twins can be greatly increased by supplementing the mother's diet (*see* DIET AND DIETETICS).

The duration of gestation varies greatly in different species, from 19 days in the mouse to 21 months in the Asiatic elephant. While in general the duration of gestation increases with the size of the species and with the stage of development at which the young are born, this is not invariable, for in man, with a nine-month pregnancy, the young are born in a much less advanced stage of development than in sheep, with only a five-month gestation period. In some species the implantation of the egg is delayed, increasing the duration of pregnancy. For example, in the badger fertilization occurs in August, but the egg develops only for a few days, then lies dormant, development resuming in January and birth occurring about 50 days afterward. In some bats, too, mating takes place in the autumn but young are not born until the following June; only two months are required for the development of the embryo, but ovulation and fertilization do not take place till the spring. As the time for parturition (the act of giving birth) approaches, a hormone, relaxin, takes effect and softens connective tissues; this causes relaxation of the ligaments in the pelvic region and makes the passage of the fetus easier. At the same time the cervix gradually relaxes under the influence of estrogens. This stage is marked also by a decrease in progesterone from the corpus luteum or placenta. The ratio of estrogen to progesterone increases, rendering the muscles of the uterus sensitive to secretions of oxytocin from the posterior pituitary. Oxytocin stimulates rhythmic contractions of the uterus that increase in intensity—at the same time that the vagina relaxes—eventually expelling the fetus (*see* CHILDBIRTH). After parturition the thick muscular walls of the uterus undergo involution, and normal estrous cycles are resumed again. In some species, such as the cow, normal cycles occur during lactation, but in others, such as the sow, they are not resumed until after weaning.

In the widest sense the process of reproduction is not complete until the adult form of the animal has been reproduced: this part of the process, however, is generally referred to as growth (*q.v.*). *See* EMBRYOLOGY AND DEVELOPMENT, ANIMAL; *see* also references under "Reproduction" in the Index.

REPRODUCTIVE SYSTEM. The human reproductive system, which is the subject of this article, comprises the organs, glands, secretions and other elements of reproduction. Since in some parts of its course the reproductive system shares certain structures with the urinary system, the two are commonly referred to in medical practice as the genitourinary or urogenital system. Allied information will therefore be found in the article URINARY SYSTEM.

The present article deals chiefly with three main topics: (1) the anatomy and physiology of the male and female reproductive systems; (2) the diseases of these systems and their treatment; (3) the surgery of the male system. Surgery of the female system is discussed in GYNECOLOGY, which is a general discussion of disorders of the female reproductive tract. Related information appears in ENDOCRINOLOGY; FERTILITY AND FECUNDITY; HORMONES; PREGNANCY; REPRODUCTION; SEX.

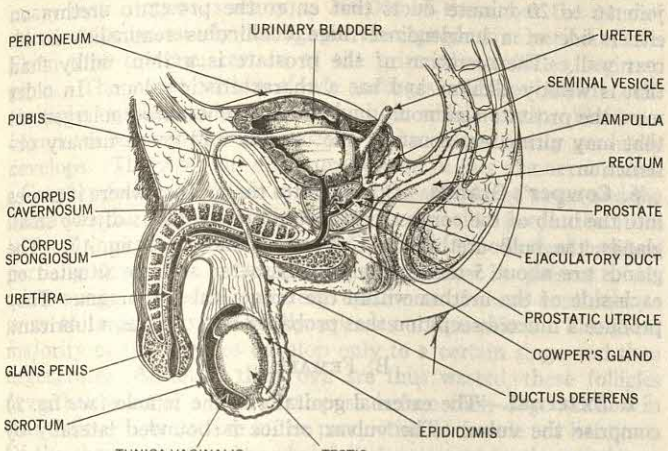
I. ANATOMY AND PHYSIOLOGY

A. MALE

The external genitalia of the male consist of the penis, the erectile copulatory organ; and the scrotum, a loose pouch of skin just beneath the base of the penis (*see* fig. 1). Within the scrotum are the gonads, or testes, which produce the male germ cells, called spermatozoa. The spermatozoa accumulate in a convoluted tubular organ, the epididymis, which is closely applied to the surface of the testis. From the epididymis, the germ cells pass through a muscular duct, the ductus deferens, and into the urethral canal of the penis, through which they are discharged into the female reproductive tract. Opening into the male reproductive passages are accessory glands: the seminal vesicles, prostate gland and bulbourethral (Cowper's) glands. These contribute secretions that add to the bulk of the semen and create a fluid medium favourable for transport and sustenance of the spermatozoa.

1. Penis.—The penis is made up of three cylinders of erectile tissue covered by skin and subcutaneous tissue devoid of fat. Two of these cylinders, the corpora cavernosa, are side by side, while the third, the corpus spongiosum, is underneath. The posterior ends of the two corpora cavernosa diverge at the root of the penis, becoming more and more fibrous in structure, and are attached

on each side to the inner border of the pubic arch. The corpus spongiosum ends posteriorly in a bulbous enlargement that is situated between the diverging columns of the corpora cavernosa. The head of the penis is formed by a large bell-shaped expansion



FROM C. D. TURNER, "GENERAL ENDOCRINOLOGY"; REPRODUCED BY PERMISSION OF W. B. SAUNDERS COMPANY

FIG. 1.—DIAGRAMMATIC SAGITTAL SECTION SHOWING THE RELATIONSHIP OF THE MALE REPRODUCTIVE ORGANS

of the corpus spongiosum, known as the glans. On its posterior surface are two concavities, which receive the rounded anterior ends of the corpora cavernosa. On the upper surface and sides of the penis the posterior rim of the glans projects as a well-marked ridge, the corona glandis, which is set off from the shaft by a constriction called the neck of the penis. The corpus spongiosum is traversed for its entire length by the urethra, a canal that begins at the bladder, passes downward through the prostate and pierces the urogenital diaphragm to enter the bulb of the corpus spongiosum from above. Thence it runs forward through the shaft of the penis to terminate in the external meatus, a vertical slit at the end of the glans. The penile portion of the urethra serves for passage of both urine and seminal fluid and is therefore a portion of the reproductive system that is shared with the urinary system.

The skin of the penis is thin, distensible and loosely attached to underlying structures. Near the head it forms a fold, the foreskin or prepuce, that normally covers the greater part of the glans; when this is drawn back, two folds on the undersurface of the penis are seen to unite to form a median fold, the frenulum, which is attached to the glans just below the meatus. In the depression behind the corona, the skin is reflected from the inner aspect of the prepuce onto the glans, where it forms a thin, closely adherent, transparent layer that is rich in sensory nerve endings. The prepuce is often removed surgically—a practice called circumcision (*q.v.*).

The corpora cavernosa consist of strong, fibroelastic, cylindrical sheaths; from their inner surfaces incomplete walls of connective tissue extend into the interior, dividing each corpus into a labyrinthine system of spaces or compartments. These spaces in the erectile tissue are lined with endothelium and are interposed between the arteries and the deep veins of the penis. When the penis is flaccid, the spaces in the corpora cavernosa are largely collapsed, but upon psychical or mechanical stimulation, the blood vessels supplying the penis are dilated and the influx of blood into the erectile tissue is thereby enhanced. At the same time a layer of muscle investing the posterior part of the corpora cavernosa contracts and restricts the outflow. The impounding of blood within the vascular spaces of the corpora cavernosa causes them to elongate and to become distended and stiffened, resulting in erection of the penis. The internal structure of the corpus spongiosum and glans resembles that of the corpora cavernosa, but the connective tissue trabeculae are finer and the spaces they delimit are smaller. The engorgement of this finer-meshed erectile tissue causes the enlargement of the glans and the swelling of the wall of the urethra in erection.

2. Scrotum.—The scrotum is a pouch of skin that is divided into two compartments by a wall down the middle. Each compartment contains a testis, an epididymis and a portion of the spermatic cord. The left half of the scrotum reaches a somewhat lower level than the right half. The skin contains scattered coarse hairs and well-developed sebaceous and sweat glands. The deep layers of the scrotal skin contain smooth muscle fibres forming contractive tissue, the dartos; contraction of these fibres draws up the scrotum and produces a corrugated appearance of the skin.

During development of the fetus, the scrotum arises as a pair of outpouchings of the abdominal wall called the genital swellings. The testes develop in the abdominal cavity and later descend into the genital swellings (see *Embryology* below). The vessels, nerves and ductus deferens that are drawn down with the testes constitute the spermatic cords. The two passageways in the abdominal wall through which the testes and spermatic cords enter the scrotum are called the inguinal canals. Each canal is at first widely open but eventually forms a flat-sided oblique passage in the abdominal wall about 3 cm. (1½ in.) in length. In the adult it remains a point of potential weakness in the body wall through which abdominal contents may be forced into the scrotum in the common pathological condition called inguinal hernia. In the descent of the male gonads the layers of the anterior abdominal wall are carried into the scrotum as coverings of the testes and spermatic cords. Thus the entrance to the inguinal canal, the abdominal inguinal ring, is formed by a funnel-shaped expansion of the transversalis fascia as it envelops the spermatic cord; the exit from the canal, the subcutaneous inguinal ring, is surrounded by the aponeurosis (sheet-like tendon) of the external oblique muscle.

In the scrotum, beneath the dartos, there is a thin layer of connective tissue, the external spermatic fascia, which is continuous at the subcutaneous inguinal ring with the aponeurosis of the external oblique muscle of the abdominal wall. The next deeper layer in the scrotum, the cremasteric fascia, contains bundles of muscle fibres derived from the abdominal internal oblique muscle. In fear, rage or exposure to cold, contraction of the cremasteric muscle tends to draw the testes upward toward the abdominal cavity. The next layer, the internal spermatic fascia, is relatively thin and is derived from the transversalis fascia of the abdomen. The innermost layer, the tunica vaginalis, is a double layer forming the serous investment of the testis; it is derived from the peritoneum lining the abdominal cavity. The outer, parietal layer is closely adherent to the internal spermatic fascia; the inner, visceral layer invests the testis and a portion of the epididymis.

The scrotum has a lower temperature than the body cavity, and it is believed to have a heat-regulating function. Migration of the testes to a scrotal pouch occurs only in certain mammals, and for these species it has been shown that the germinal elements of the testis produce spermatozoa only at a temperature below that of the abdominal cavity.

Testes.—The testes, or testicles, are the essential male organs of reproduction. Each is oval, about 4–5 cm. (1½–2 in.) in length and 2.5–3 cm. (1 in.) in width. The testis has a dense fibrous capsule, the tunica albuginea, from which thin walls penetrate into the interior, dividing it into about 250 compartments or lobules. Within each lobule there are from one to three highly convoluted seminiferous tubules. These join straight tubules (tubuli recti) that open into a plexus of communicating tubes, the rete testis. The spermatozoa produced in the seminiferous tubules are carried via the tubuli recti to the rete testis, and from there they pass through 15 to 20 small ducts, the efferent ductules (ductuli efferentes testis, or vasa efferentia), into the epididymis.

The microscopical seminiferous tubule has a small, irregular passage surrounded by the germinal epithelium, which is enclosed by a membrane. The germinal epithelium is composed of the germ cells in different stages of maturation (called, according to their stage of development, spermatogonia, spermatocytes, spermatids and spermatozoa) and their supporting elements, the Sertoli cells. The mature spermatozoon is a highly specialized motile cell consisting of a head, a middle piece and a long tail, or flagellum, which executes vigorous lashing movements that propel the cell forward. Spermatozoa are produced in astronomical

numbers. It has been estimated that an average man discharges 400,000,000,000 sperm in his reproductive lifetime. A single ejaculate contains hundreds of millions; yet, if fertilization is achieved, only one of this enormous number enters the ovum. The condensed nucleus in the head of the fertilizing spermatozoon contains all the hereditary material contributed by the father.

The endocrine function of the testes is believed to reside in the interstitial tissue, which is located between the seminiferous tubules. The cells of this tissue produce the male sex hormone responsible for maintenance of accessory reproductive organs and development of secondary sex characteristics such as deep voice, beard, muscular build, etc.

Epididymis.—The epididymis is a firm, elongated body closely adhering to the posterior surface of the testis. At the upper pole it is enlarged to form the head, and at the lower pole there is a lesser enlargement, the tail. The entire epididymis consists of an extremely tortuous tube that is 15 to 20 ft. long when extended. Because of its great length it can accommodate a large number of spermatozoa. The cells lining this convoluted tube are believed to produce a secretion that plays a role in the nutrition of the spermatozoa.

3. Ductus Deferens.—The ductus deferens (or vas deferens) is the continuation of the tube of the epididymis. It extends from the tail of the epididymis to the posterior surface of the prostate, where it joins the duct of the seminal vesicle to form the ejaculatory duct (*see* fig. 1). The ductus deferens ascends from the epididymis to the subcutaneous inguinal ring, being joined in this part of its course by testicular arteries, veins, lymphatics and nerves to form the spermatic cord. These structures pass obliquely through the abdominal wall, via the inguinal canal. At the abdominal inguinal ring they separate, the ductus passing down the side of the pelvis and then turning inward along the back wall of the bladder to the prostate, where it meets its fellow of the opposite side. The ductus deferens has a thick muscular wall with a uniform diameter of about 3 mm. ($\frac{1}{10}$ in.) until it reaches the seminal vesicle; there it broadens out and forms the ampulla of the ductus deferens, the lumen of which has numerous outpocketings. Immediately before joining the excretory duct of the seminal vesicle, the ductus deferens again becomes round and slender.

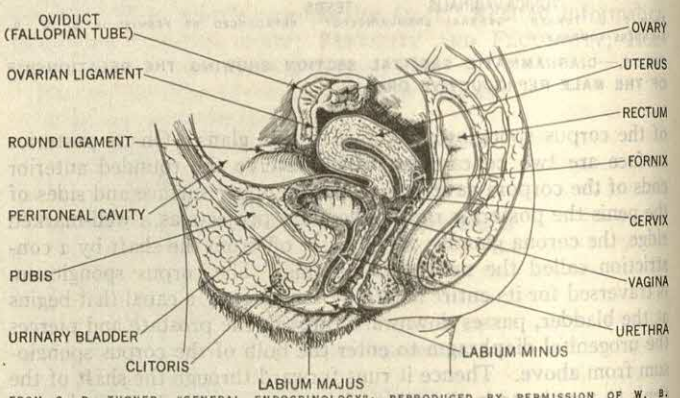
4. Seminal Vesicles and Ejaculatory Ducts.—The seminal vesicles are two saclike appendages of the ductus deferens that are fixed to the rear surface of the bladder and lie lateral and parallel to the corresponding ductus deferens. Each vesicle is composed of a thin-walled tubular structure, 10 to 12 cm. (about 4 in.) long, folded back and forth upon itself and enclosed in a fibromuscular capsule. Arising from the main tube are numerous pouches (sacculations or diverticula). The excretory duct of the seminal vesicle on each side joins the ductus deferens to form an ejaculatory duct. The two ejaculatory ducts are narrow, have thin walls and run side by side through the prostate gland to open into the urethra. The seminal vesicles were formerly regarded as seminal receptacles for the storage of semen, but according to the modern view their function is purely glandular and they do not store semen. The principal reserves of spermatozoa are contained within the epididymis, and those that are to be delivered in any one ejaculation accumulate in the ampulla of the ductus deferens just prior to ejaculation. Here, in the secretion of the ampulla, the spermatozoa first come into contact with fructose, the principal carbohydrate substrate for their metabolism, and it is probable that sperm motility is initiated at this time. The main source of fructose is in the secretion of the seminal vesicles, which is discharged in the process of ejaculation into the prostatic urethra together with the secretion of the prostate and the spermatozoa contained in the ampulla. In man, the greater part of the volume of the ejaculate is derived from the secretion of the seminal vesicles.

5. Prostate.—The prostate is situated just below the bladder and is traversed by the urethra and the ejaculatory ducts. It is pyramidal in form, with the base upward in contact with the floor of the bladder. The vertical dimension is from 2.2 to 3 cm. (1 to $1\frac{3}{8}$ in.), the transverse diameter from 3.5 to 4 cm. ($1\frac{3}{8}$ to $1\frac{3}{4}$ in.) and the thickness from 2 to 2.5 cm. ($\frac{4}{5}$ to 1 in.). The prostate is composed of glandular tissue enclosed in a dense fibrous capsule. Microscopically it consists of 30 to 50 branching tubuloalveolar glands embedded in a tissue rich in smooth muscle fibres, which aid in discharging the prostatic fluid in ejaculation. The glands join 16 to 20 minute ducts that enter the prostatic urethra on either side of a longitudinal ridge (colliculus seminalis) in its rear wall. The secretion of the prostate is a thin, milky fluid that is weakly alkaline and has a characteristic odour. In older men, the prostate commonly undergoes a generalized enlargement that may ultimately constrict the urethra and cause urinary obstruction.

6. Cowper's Glands.—Opening into the urethra where it passes into the bulb of the corpus spongiosum are the ducts of two small glands, the bulbourethral or Cowper's glands (*see* fig. 1). The glands are about 5 mm. ($\frac{1}{5}$ in.) in diameter and are situated on each side of the urethra within the urogenital diaphragm. They produce a mucoid secretion that probably functions as a lubricant.

B. Female

1. External.—The external genitalia in the female (*see* fig. 2) comprise the vulva. The vulvar orifice is bounded laterally by



FROM C. D. TURNER, "GENERAL ENDOCRINOLOGY"; REPRODUCED BY PERMISSION OF W. B. SAUNDERS COMPANY

FIG. 2.—DIAGRAMMATIC SAGITTAL SECTION SHOWING THE ARRANGEMENT AND RELATIONSHIP OF THE FEMALE REPRODUCTIVE ORGANS

the labia majora, two prominent rounded folds of skin that correspond to the scrotum of the male. They have a sparse covering of hair and meet in the midline so that they largely conceal the other external genital structures. Between the labia majora are a pair of pendulous skin folds, the labia minora, that enclose a shallow elliptical depression called the vestibule. Toward the front the labia minora are continuous with one another, forming the prepuce, a thin fold of skin that covers the sensitive clitoris. The clitoris is a rudimentary erectile organ, the counterpart of the penis of the male. Opening into the vestibule below it are the urethra, the urinary passage from the bladder; and the vagina, the flattened fibromuscular tube that receives the penis during copulation. In virgins, the entrance of the vagina is narrowed by a circular fold of mucous membrane called the hymen.

2. Internal.—The internal reproductive organs consist of the female gonads, or ovaries, located within the body cavity and a system of tubular organs that communicate with the exterior at the vaginal orifice. Egg cells, or ova, are produced in the ovaries and are released singly at monthly intervals. Closely associated with the ovaries are the open ends of the right and left oviducts (Fallopian tubes). At the time of ovulation either of these may receive the ovum. If coitus occurs, the ovum may be fertilized by one of the spermatozoa reaching the upper part of the oviduct. The developing ovum then passes down through the oviduct to the cavity of the uterus, or womb, where it becomes implanted and is nourished until birth. The lower end of the uterus projects into the upper end of the vagina. The dilated neck of the uterus and the vagina constitute the birth canal, through which the infant emerges at the termination of pregnancy (*see* CHILDBIRTH).

Ovaries.—The mature ovary is a firm organ about the size of a large almond shell, with a scarred or wrinkled exterior (*see* fig. 2). Its surface is covered by a layer of low cuboidal cells forming

the germinal epithelium. Near the surface are many minute egg cells that have remained dormant since birth. Each is surrounded by a layer of flattened follicle cells. An ovum and its covering layer of cells form a primordial follicle. In a young adult woman each ovary may contain as many as 200,000 of these, but the number decreases progressively throughout the reproductive period of life. From time to time, certain of the primordial follicles begin to grow. The ovum within slowly enlarges and the follicle cells multiply rapidly, giving rise to a thick cellular wall. Fluid accumulates between the follicle cells, and a central cavity gradually develops. The vesicular structure formed in this manner is called a Graafian follicle. Within it the eccentrically placed ovum and the cells immediately surrounding it form a domelike projection from the wall into the fluid-filled cavity (*see* fig. 3). Several hundred partially developed follicles of this kind may be present in an adult ovary. In each ovulatory cycle one of these continues to grow to large size and finally releases a ripe ovum. The great majority of the follicles develop only to a certain stage and then degenerate. Although their ova are thus wasted, these follicles nevertheless serve a useful purpose before their degeneration in that their cells are active in the production of female sex hormone. Of the thousands of primordial follicles present in the ovaries at birth, fewer than 400 are likely to produce mature ova during a woman's reproductive life.

Oviducts (*Fallopian Tubes*).—The oviduct is a sinuous tube of involuntary muscle, 10–13 cm. (4–5 in.) long, running laterally from ovary to uterus (*see* fig. 2). It is lined by an extensively folded mucous membrane. Near the ovary the open end of the oviduct is expanded into a thin-walled, funnel-shaped structure, the infundibulum. Its edges are prolonged into a number of slender, tapering processes called fimbria, some of which are attached to the ovary. The shape and position of the oviduct are changed by contractions in its muscular wall. It is particularly active at the time of ovulation, when it becomes reddened from dilatation of all its blood vessels and moves so as to bring its open fimbriated end into close apposition with the surface of the ovary, thus facilitating the passage of the ovum directly into the infundibulum. The passage of the oviduct narrows and becomes very small where it passes through the thick, muscular, uterine wall. Ciliated cells lining the oviduct maintain a constant slow movement of fluid from the body cavity toward the uterus.

Uterus.—The uterus, when not pregnant, resembles a flattened pear in size and shape, with the stem end directed downward toward the vagina (*see* fig. 2). The body of the uterus, the corpus uteri, is usually bent forward so that it lies upon the urinary bladder and is thus at an angle to the cylindrical neck, the cervix uteri. The thick wall of the uterus is composed largely of involuntary muscle. The uterine cavity is flattened from front to back and is roughly triangular in form, with the upper angles extending out toward the openings of the oviducts, and the lower angle directed downward toward the cervix (*see* fig. 3). The lining of the corpus uteri, the endometrium, is a mucous membrane specially adapted for the reception and sustenance of the fertilized ovum. It is covered by a single layer of ciliated and secretory cells that is continuous with the lining of many simple tubular glands that extend from the surface of the endometrium down to the muscle of the uterine wall. The glands are embedded in a loose connective tissue richly supplied with blood vessels. The cervix of the uterus has a slender cavity narrowed by projecting folds of mucous membrane. Opening into it are numerous branching, mucus-secreting glands. At its lower end the cervical canal communicates with the vagina through a narrow slit, the external os.

Attachments.—The attachments of the ovaries, oviducts and uterus support them, while at the same time permitting their independent movement and allowing for enlargement of the uterus in pregnancy. The principal support for all three organs is provided by the two broad ligaments. Each of these consists of a double layer of peritoneum extending from the sides of the uterus to the lateral wall of the pelvis. The blood vessels, lymphatics and nerves reach the uterus by passing between the layers of the broad ligaments. Each ovary is suspended from the back of the broad ligament by a fold of peritoneum, the mesovarium. A small peritoneal fold also passes upward from the tubal end of the ovary to the pelvic wall. This is the infundibulopelvic ligament. Through it, blood vessels reach the ovary from above. The ovarian and uterine vessels communicate within the broad ligament, and blood can reach these organs via either route. The medial pole of the ovary is attached to the uterus by a stout band of connective tissue, the ovarian ligament. A fibrous cord, the round ligament, runs laterally from the uterus to the wall of the pelvis; from there it passes anteriorly through the abdominal wall via the inguinal canal and terminates in the skin and subcutaneous connective tissue of the labia majora. The round ligament in the female corresponds to the gubernaculum in the male, the fibrous band that attaches the lower pole of the testis to the skin of the scrotum. The cervix of the uterus is held back by the uterosacral ligaments, two folds of fascia and peritoneum that run from the back of the cervix around the rectum on either side to attach to the fascia over the anterior surface of the sacrum.

C. Reproductive Function in Woman

During childhood there are no signs of activity in the female genital organs, but at the beginning of adolescence (8 to 12 years) the ovaries are activated by the hormones of the pituitary gland (hypophysis) to begin the production of large follicles, which in turn secrete ovarian hormone. The latter is carried in the blood stream and stimulates development of all parts of the reproductive tract. In addition, the bony pelvis, breasts, hair and fat depots begin their progress toward maturity. There is a rhythmic alternation in the dominance of the hormones of the hypophysis and ovary. Eventually the hormonal tides attain a height that results in bleeding from the endometrium and the first menstrual flow occurs (*see* Menstruation).

During the childbearing period of life the sequence of events in the cycle is usually as follows: at intervals of about a month, under stimulation from the hypophysis, one ovarian follicle outstrips its fellows in growth. In a few days it attains a diameter of about 1.25 cm. ($\frac{1}{2}$ in.) and protrudes from the ovary like a clear blister. Usually only one follicle at a time enters upon this final growth period, but occasionally more may develop; if the ova produced are fertilized, multiple births may result. At ovulation the ripened egg cell loosens from the wall of the large follicle and soon the wall bulges, breaks and the viscid follicular fluid wells out, carrying the ovum along with it. At this time of the cycle, the level of ovarian hormone circulating in the blood stream reaches a peak, and the oviducts and uterus are stimulated to greater activity. It has been possible to peer into the body cavity through an endoscope at such a time and see the fimbriated end of the oviduct wrapped closely about the ovary while the organs move rhythmically. The close joining of the open end of the infundibulum to the ovary facilitates the entrance of the ovum into the

oviduct. If spermatozoa are present, the egg may be fertilized almost as soon as it is liberated from the follicle. In any case it is swept into the oviduct by ciliary action and is slowly moved along by peristaltic contractions, reaching the uterus about the fourth day after ovulation.

In the interim, the uterine endometrium has grown thick through cell division and accumulation of interstitial fluid, and its glands have increased in length and complexity. This preliminary period of preparation of the uterus for reception of the ovum is called the follicular phase of the cycle because it is dominated by the hormone produced by the growing follicles. Ovulation is expected to occur on about the 14th day of a 28-day cycle, but it may occur as early as 7 days after the beginning of menstruation or may be delayed for 18 days or more. The period of the cycle subsequent to ovulation is called the luteal phase because it is dominated by the hormone produced by the corpus luteum, or yellow body, an organ of internal secretion that arises in the ovary from the wall of the ruptured follicle. Immediately after ovulation, while the egg is still in the oviduct, the thin wall of the collapsed follicle thickens rapidly and its cells undergo a marked change in their appearance. A meshwork of thin-walled capillary vessels develops between them, and the entire structure is transformed into a conspicuous yellow body grossly visible in the ovary at the site formerly occupied by the follicle.

The hormone secreted by the cells of the corpus luteum produces further changes in the uterus that make it a most favourable site for implantation and nourishment of the embryo. Under its influence the contractions of the uterus are slowed down; the endometrium thickens and its arteries lengthen and become more coiled; its glands grow more contorted and are distended with a secretion rich in nutrient substances. These changes take place whether the egg has been fertilized or not.

If conception does not occur, the corpus luteum remains active for only 10 to 14 days. With the decline in its hormone output, the blood flow to the uterus is reduced and the endometrium begins to shrink. Its superficial zone suffers particularly, for it is supplied by the coiled arteries, which, at this time, begin to constrict intermittently. The walls of the superficial vessels are damaged and ultimately break down, permitting blood to seep out into the surrounding tissue. The extravasated blood at first accumulates within the endometrium but finally drains into the cavity of the uterus. This marks the beginning of menstruation. The blood-soaked, degenerating tissue soon loosens and sloughs off, leaving a raw surface. The greater part of the thickness of the endometrium degenerates and is lost during menstruation, but the bases of the glands persist, and the multiplication and migration of their cells quickly restores the surface layer after menstruation is over. A period of relative inactivity may ensue before another set of ovarian follicles enter upon their final growth and release the follicular hormone that stimulates anew the growth in thickness of the endometrium.

Menstrual cycles continue more or less regularly unless interrupted by pregnancy. They are accompanied by various general bodily changes. At the middle of the cycle a sudden slight fall, followed by a rise, in the basal body temperature may be detected. Rarely abdominal pain may be experienced at the time of ovulation. The relations between hypophysis and ovary may be affected by other hormones and by the nervous system as well. Changes in climate, living conditions, infections or psychic disturbances may consequently affect the reproductive cycle. When the responses of the ovaries begin to wane at the age of 45 to 50 years, the hormonal balance is upset and changes occur in the economy of the body as a whole. These give rise to the characteristic symptoms of the menopause (*q.v.*), or change of life.

(D. W. Fr.)

D. Embryology

The development of the reproductive organs (*see* fig. 4) is closely interwoven with that of the urinary system. It is convenient to take up the development at the stage in which the genital ridge is seen on each side of the attachment of the mesentery; external to this, and forming another slight ridge of its own, is the Wolffian duct, while, a little later, the Müllerian duct is formed and lies ventral to the Wolffian. Until the fifth or sixth week the development of the genital ridge is very much the same in the two sexes and consists of cords of cells growing from the epithelium-covered surface into the mesenchyme, which forms the interior of the ridge. In these cords are some large germ cells that are distinguishable at a very early stage of development. The germinal epithelium covering the ridge, and the mesenchyme inside it, are both derived from the mesoderm, or middle layer, of the embryo.

About the fifth week of embryonic life the tunica albuginea appears in the male, from which septa grow to divide the testis into lobules, while the epithelial cords form the seminiferous tubes, though these do not gain a lumen until just before puberty. From the adjacent mesonephros, or perhaps coelomic epithelium, cords of cells grow into the attached part of the genital ridge, or testis, as it now is, and from these the rete testis is developed.

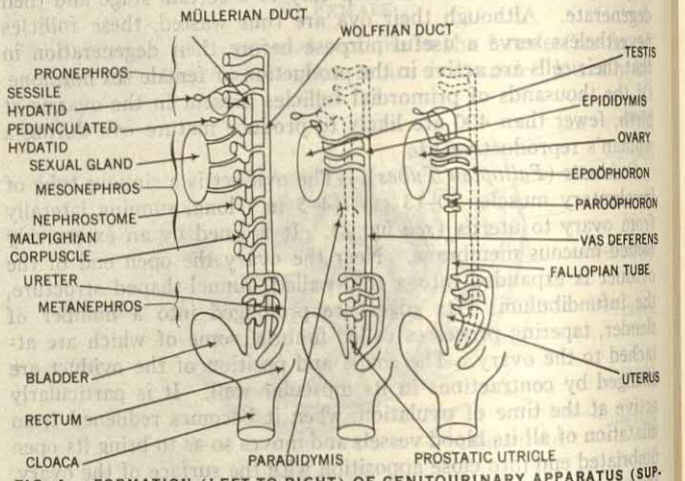

FIG. 4.—FORMATION (LEFT TO RIGHT) OF GENITOURINARY APPARATUS (SUPPRESSED PARTS ARE DOTTED); UNDIFFERENTIATED, MALE AND FEMALE

In the female the same growth of epithelial cords into the mesenchyme of the genital ridge takes place, but each one is distinguished by a bulging toward its middle; only here are the large germ cells found. Eventually this bulging part is broken up into a series of small portions, each of which contains one germ cell or ovum and gives rise to a Graafian follicle. Mesonephric cords appear as in the male; they do not enter the ovary, however, but form a transitory network (rete ovarii) in the mesovarium.

As each genital gland enlarges it remains attached to the rest of the intermediate cell mass by a constricted fold of the coelomic membrane, known as the mesorchium in the male and the mesovarium in the female. Lying dorsal to the genital ridge in the intermediate cell mass is the mesonephros, consisting of numerous tubules that open into the Wolffian duct. This at first is an important excretory organ but during development it becomes used for other purposes. In the male, as has been shown, it may form the rete testis and certainly forms the vasa efferentia and globus major of the epididymis; in addition, some of its separate tubes probably account for the aberrant ducts and the paradidymis, or organ of Giraldès. In the female the tubules of the epoöphoron represent the main part, while the paroöphoron, like the paradidymis in the male, is probably formed from some separate tubes.

The Wolffian duct, which in the early embryo carries the excretion of the mesonephros to the cloaca, forms eventually the body and tail of the epididymis, the ductus deferens and ejaculatory duct in the male, the seminal vesicle being developed as a pouch in its course. In the female this duct is largely done away with, but it remains as the collecting tube of the epoöphoron and in some mammals as the duct of Gartner, which runs down the side of the vagina to open into the vestibule.

The Müllerian duct, as it approaches the cloaca, joins its fellow of the opposite side, so that there is only one opening into the ventral cloacal wall. In the male only the lower part of it

remains as the prostatic utricle, but in the female the Fallopian tubes, uterus and probably the vagina are all formed from it. In both sexes a small hydatid, or vesicle, is liable to be formed at the beginning of both the Wolffian and Müllerian ducts; in the male these hydatids are close together in front of the globus major of the epididymis and are known as the sessile and pedunculated hydatids of Morgagni. In the female there is a hydatid among the fimbriae of the Fallopian tube, which of course is Müllerian and corresponds to the sessile hydatid in the male, while another is often found at the beginning of the collecting tube of the epoöphoron and is probably formed by a blocked mesonephric tubule. This corresponds to the pedunculated hydatid of the male. The development of the vagina is peculiar. Instead of the two Müllerian ducts joining to form the lumen of its lower third, as they do in the case of the uterus and its upper two-thirds, they become obliterated, and their place is taken by two solid cords of cells, which later became canalized, while the septum between them is obliterated.

The common chamber, or cloaca, into which the alimentary, urinary and reproductive tubes open in the fetus has the urinary bladder (the remains of the allantois) opening from its ventral wall.

During development the alimentary or anal part of the cloaca is separated from the urogenital. According to F. Wood Jones, the anal part is completely shut off from the urogenital and ends in a blind pouch that grows toward the surface and meets a new ectodermal depression, the permanent anus, which is a new perforation and not a part of the original cloacal aperture. This description is in harmony with the malformations occurring in this region.

The external generative organs at first have the same appearance in the two sexes and consist of a swelling, the genital eminence, in the ventral wall of the cloaca. This in the male becomes the penis and in the female the clitoris. Throughout the generative system the male organs depart most from the undifferentiated type, and in the case of the genital eminence two folds grow together and enclose the urogenital passage, thus making the urethra perforate the penis, while in the female these two folds remain separate as the labia minora. In the male the folds sometimes fail to unite completely and then there is an opening into the urethra on the undersurface of the penis—a condition known as hypospadias.

In the undifferentiated condition the integument surrounding the genital opening is raised into a horseshoelike swelling with its convexity over the pubic symphysis and its concavity toward the anus; the lateral parts of this remain separate in the female and form the labia majora, but in the male they unite to form the scrotum. The median part forms the mons veneris, or mons pubis.

It has been shown that the testis is formed in the loin region of the embryo close to the kidney, and only in the later months of fetal life does the testis move downward into the scrotum (see *Scrotum* above). In the lower part of the genital ridge a fibromuscular cord is formed that stretches from the lower part of the testis to the bottom of the scrotum; it is known as the gubernaculum testis, and by its means the testis is directed into the scrotum. Before the testis descends, a pouch of peritoneum called the processus vaginalis passes down in front of the gubernaculum through the opening in the abdominal wall (which afterward becomes the inguinal canal) and into the scrotum; behind this the testis descends, carrying with it the mesonephros and mesonephric duct. These, as has already been pointed out, form the epididymis and ductus deferens. At the sixth month the testis lies opposite the abdominal ring, and at the eighth it reaches the bottom of the scrotum and invaginates the processus vaginalis from behind. Soon after birth the communication between that part of the processus vaginalis that now surrounds the testis and the general cavity of the peritoneum disappears, and the part that remains forms the tunica vaginalis. Sometimes the testis fails to pass beyond the inguinal canal, resulting in the condition known as cryptorchidism.

In the female the ovary undergoes a descent like that of the testis, but it is less marked since the gubernaculum becomes attached to the Müllerian duct where that duct joins its fellow to form the uterus. Thus, the ovary does not descend lower than the level of the top of the uterus, and the part of the gubernaculum running between it and the uterus remains as the ligament of the ovary, while the part running from the uterus to the labium is the round ligament. In rare cases the ovary may be drawn into the labium just as the testis is drawn into the scrotum.

II. DISEASES AND THEIR MEDICAL TREATMENT

The male and female gonads, *i.e.*, the testes and ovaries, have a dual function: (1) they are the glands of internal secretion that determine the normal growth, development and maintenance of the physical characteristics of maleness and femaleness; and (2) they produce the gametes (*i.e.*, spermatozoa and ova), which are responsible for reproduction. Disorders of the testes and ovaries may cause subnormal, excessive or untimely secretion of hormones and may adversely affect the reproductive function, leading to sterility. Gonadal diseases are caused by abnormal sexual differentiation, congenital anomalies, deficient pituitary function, infections and tumours. Disorders of the strength or direction of the sexual impulse generally are caused not by organic diseases of the gonads but rather by environmental difficulties, usually beginning early in life.

1. Abnormal Sex Differentiation.—Sex in man is largely determined by the chromosomal constitution of somatic (body) cells. Each cell of the normal human organism contains 46 chromosomes (44 autosomes and one pair of sex chromosomes, designated as 44 + XY in the male and 44 + XX in the female). If, during development of the gametes, an X or a Y chromosome is lost, or if reduction division (meiosis) is abnormal during gametogenesis, a sperm or an ovum lacking a sex chromosome will result. An abnormal number of sex chromosomes may also result from an error of cell division in the fertilized zygote. The ensuing anomalies of chromosomal number are associated with the so-called disorders of chromosomal sex (*see* below). The effects of the chromosomal abnormalities become manifest early in fetal life. Fetal sex differentiation takes place in three successive steps: (1) gonadogenesis; (2) development of the genital ducts; and (3) development of the urogenital sinus and the external genitalia. The primordial gonad and accessory sex apparatus have bisexual potentialities. In the presence of a Y (male) chromosome, the gonad differentiates into a fetal testis, which secretes a substance or substances that in turn determine the differentiation of the embryo into a male. In the absence of a Y chromosome, as in the normal female fetus, the embryo follows its inherent tendency to become feminized.

Turner's Syndrome.—This condition can be looked upon as an example of abnormal sex differentiation. Persons with this disorder are apparent (phenotypic) females but lack the normal female chromosomal constitution. They generally have only 45 chromosomes: (44 + X0); internal genitalia are female in type but the ovaries are rudimentary, consisting of ridges of connective tissue. These undifferentiated gonads produce no ova and virtually no female hormone, so that the patients remain sexually infantile and sterile. Associated features are short stature and anomalies of the cardiovascular system and the skeleton. In rare instances, other types of chromosomal complements are found. Treatment of this disease, which occurs in about one of 3,000 phenotypic females, consists of substitution therapy with female hormones (natural or synthetic estrogens). The hormones stimulate moderate growth and development of secondary sex characters; there is no way to correct the sterility.

Klinefelter's Syndrome.—Persons with this defect are phenotypic males. The disorder occurs in approximately 1 in 400 newborn males. The chromosomal abnormality consists of an excessive number, 47; the chromosomal complement is typically 44 + XXY. Less frequently, 48 or 49 chromosomes are present, composed of 44 + XXXY or 44 + XXXXY; individuals with 48 or 49 chromosomes are mentally retarded. The constant clinical features of the syndrome are infertility and small testes. These

testes may secrete normal or profoundly subnormal amounts of male hormone (testosterone), resulting in normal or deficient virilization (eunuchoidism). Whether the internal secretion (*i.e.*, Leydig cell function) of the testis is normal or deficient, the gametogenic function is absent. The seminiferous tubules are small, underdeveloped or even rudimentary and generally undergo degenerative changes at puberty. Spermatozoa are not elaborated and sterility is the rule. The testicular lesion is a consequence of the chromosomal abnormality. The single Y chromosome is a sufficiently strong determinant of maleness so that the embryonic gonad differentiates into a testis and the fetus becomes more or less completely masculinized. Associated abnormalities are failure of the testes to descend into the scrotum (cryptorchidism), abnormal position of the urethra (hypospadias), excessive development of breast tissue (gynecomastia) and, rarely, mongolism and leukemia. If deficient virilization is apparent at or after the expected time of puberty, treatment with male hormone (testosterone) promotes satisfactory growth and development of secondary sex characters so that normal sexual performance becomes possible. As in Turner's syndrome the sterility cannot be corrected.

2. Congenital Anomalies.—Developmental defects of the genital system are relatively common congenital malformations. Such defects are frequently associated with malformations of the urinary tract because of the close association of the genital and urinary systems in embryogenesis. Congenital anomalies of the gonads occur infrequently. Probably the most common congenital abnormality of the gonads is cryptorchidism, or failure of the testes to descend into the scrotum. This abnormality occurs in 0.2% to 0.4% of adult males. The cause is disputed; the two most likely are mechanical abnormalities (*e.g.*, hernia) that impede the descent of a normal testis, or, more commonly, a developmental defect in the testis itself. Failure to descend may be unilateral or bilateral; the abnormally placed gonad may be in the inguinal canal (groin) or in the abdominal cavity. The chief danger arising from the misplaced testis is a very much higher incidence of cancer. Efforts should therefore be made to bring undescended testes into the scrotum; in addition to preventing the development of cancer, such action also will preclude the degeneration of spermatogenic function with resultant sterility owing to the higher temperature of an extrascrotal environment. Although ideal treatment is controversial, a reasonable practice is to attempt to stimulate growth of the testis at the age of 8 to 11. This is done by administering gonad-stimulating hormone derived from human pregnancy urine (human chorionic gonadotrophin) for a few weeks. If descent does not occur, it is then necessary to resort to surgical methods.

True hermaphroditism, or intersexuality, is an extremely rare condition characterized by varying degrees of ambisexual differentiation of the gonads and accessory sexual apparatus. The body form may be predominantly male, predominantly female or ambiguous. The chromosomal constitution is either normal male or, more commonly, normal female. In order to establish the diagnosis it is frequently necessary to explore the abdomen and locate and identify the gonads, which may consist of an ovary on one side and a testis on the other, or a gonad containing both testicular and ovarian elements (ovatestis) on one or both sides. Since such gonads tend to become cancerous, it is necessary to remove them. Sexual development is then brought about by administration of either male or female hormone. The decision whether to give testosterone or estrogen depends upon the structure of the external genitalia and the sex in which the patient has been reared. This problem is easiest to solve if the ambiguous sex is recognized early in infancy. Plastic surgical reconstruction is then done in an effort to preserve the dominant sex.

Intersexes may be further subdivided into two categories: (1) male pseudohermaphrodites when the gonads are testes, and (2) female pseudohermaphrodites when the gonads are ovaries.

In male pseudohermaphrodites (syndrome of feminizing testes) the occurrence is familial and the patients appear to be normally developed females, but the chromosomal sex is 44 + XY (normal male) and the gonads are well-developed testes located in the abdomen or elsewhere. The clinical features result from failure of the abnormal fetal testis to bring about complete masculine differentiation of the genital ducts or external genitalia. After puberty, the testis secretes estrogen in an amount comparable to that produced by adult women. Anatomically, the patients look like normal women, but the internal genital ducts are primarily male, and sexual hair is sparse. Since these gonads are apt to form cancers, they should be removed surgically, and since the disease is generally recognized at or after puberty, when female behaviour patterns have become fixed, female sexual characters are maintained by the administration of estrogenic hormones.

The two principal forms of female pseudohermaphroditism are associated with (1) congenital adrenal cortical hyperplasia and (2) exposure of the fetus to androgens from the maternal circulation.

Congenital adrenal cortical hyperplasia is the most common form of female pseudohermaphroditism and accounts for at least half the cases of ambiguous external genitalia. The disorder is genetically determined. The patients are chromosomal females (44 + XX) who resemble normal females but display varying degrees of masculinization of the external genitalia. The chemical basis of the disease is defective synthesis by the adrenal gland of its principal, life-maintaining hormones. This deficiency results in overproduction by the pituitary of adrenocorticotrophin, or ACTH, a hormone that stimulates the adrenal so that it grows to a very large size and secretes enormous quantities of androgenic (male-inducing) steroids. This process begins early in fetal life; varying degrees of masculinization of the internal and external genitalia ensue. If treatment is not started in early childhood, growth of the bones stops prematurely, resulting in short stature, failure of secondary sex characters (viz., breast growth, menstruation) to develop, and the appearance of such masculine features as deepening of the voice, increased body hair and beard growth. Effective treatment can be achieved by administration of those adrenal cortical hormones that the gland cannot synthesize (*e.g.*, hydrocortisone). These hormones suppress the pituitary so that its stimulus to adrenal production of androgenic hormones is minimized. This form of therapy occasionally permits normal female development even to the point of normal conception and pregnancy. Often, however, full development of secondary sex characters and menstruation requires the administration of estrogens.

The less common form of female pseudohermaphroditism occurs in a child when testosterone, natural or synthetic progestational hormones or synthetic estrogens are administered to the mother during the first three weeks of pregnancy; rarely, the condition is associated with the presence in the mother of a masculinizing tumour of the ovary or the adrenal. The patients are females with more or less ambiguous genitalia; no treatment with hormones is needed, and normal female development occurs at the usual age of puberty. (*See* also HERMAPHRODITE.)

3. Deficient Pituitary Function.—*Precocious and Delayed Puberty.*—Normal growth of the gonads and normal hormone secretion by the gonads are dependent upon normal function of the anterior lobe of the pituitary gland, which secretes at least two hormones that influence gonadal activity (*see* PITUITARY GLAND). Two mechanisms regulate the secretion of these pituitary hormones: (1) the influence of the brain and (2) the quantity of gonadal hormone circulating in the blood. The higher the blood level of gonadal hormone, the smaller the amount of pituitary hormone secreted. A delicate balance of these factors is required for the normal occurrence of adolescence and for the normal maintenance of the menstrual cycle. Any structural lesions (*e.g.*, tumour, inflammation) of the brain centres that influence the release of pituitary hormones will materially delay or accelerate the onset of puberty.

Delay in the onset of puberty in boys or girls may not be due to any detectable cause. The delay may result from tumours that destroy the pituitary itself, or from malnutrition or severe debilitating illnesses. Finally, delayed puberty may be caused by primary diseases of the gonads. Treatment consists of detection and removal of tumours of the brain or pituitary, or treatment

of the underlying systemic disorder. In the majority of cases, where no definite cause can be found, the appropriate sex hormone or gonad-stimulating hormone is given; a short course of treatment is often followed by the onset of spontaneous pubertal development.

Precocious puberty (*i.e.*, puberty starting before the age of ten years in either sex) is caused by a great variety of disorders; in many instances, there is no discernible cause. In both sexes, precocious puberty may accompany organic lesions of the brain, *e.g.*, encephalitis, congenital defects and tumours of the basal portions of the brain or pineal body (also called the epiphysis, or pineal organ).

Congenital adrenal hyperplasia in the male, the counterpart of the major cause of female pseudohermaphroditism in girls, is the commonest cause of sexual precocity; treatment consists of pituitary-adrenal suppression by administering cortisone or related hormones. A rare cause in boys is interstitial cell tumour of the testis, usually benign and curable by surgical removal. In girls, sexual precocity may be associated with estrogen-secreting granulosa cell tumour of the ovary, or with rare tumours of the adrenal gland that may secrete estrogens (or, more commonly, androgens, resulting in virilization). Treatment consists of surgical removal of the tumours.

Pituitary-Adrenal Relationships in Adult Life.—Failure of pituitary function in the adult is most commonly the result of tumours of the gland, of vascular injury to it after a catastrophic delivery, or of severe malnutrition. Treatment consists of X-radiation of tumours, or, if that fails, surgical removal. Gonadal deficiency due to pituitary failure can be effectively treated by administration of testosterone or estrogen, but there is no treatment for the ensuing infertility.

4. Infections and Tumours of the Gonads.—Infections of the testis occasionally cause sterility. The commonest testicular infection is the acute orchitis of mumps; this is a frequent, painful complication of mumps that is followed in almost half the cases by some degree of testicular atrophy but only infrequently by sterility since the involvement of the gland is spotty. Chronic orchitis is usually painless and is a result of syphilis, tuberculosis, leprosy and certain parasitic diseases. Treatment of the infectious disease usually fails to restore the reproductive function of the gland. Infections of the ovary include mumps oöphoritis and abscesses of the ovary due to gonorrhea. The latter are effectively treated with penicillin.

Tumours of the testis comprise only 2% of all forms of cancer in the male but they are frequently malignant. Very rarely, they are benign and hormone-secreting (*e.g.*, the interstitial cell tumour); the usual forms are the so-called germinal tumours (*e.g.*, seminoma, teratoma) that occur with increased frequency in the testes of intersexes and in undescended (cryptorchid) testes. These malignant tumours may or may not be amenable to X-ray treatment.

The ovary is the site of a great variety of tumours, benign or malignant; treatment is generally surgical unless cancer is present and has spread, in which case X-radiation may be used. A few of these ovarian growths are hormone-secreting: granulosa-cell tumours secrete estrogens and are a rare cause of sexual precocity; arrhenoblastomas and adrenal cortical-like tumours secrete androgens and cause failure of menstruation and masculine changes; and ovarian struma may contain enough functioning thyroid tissue to bring about the clinical picture of hyperthyroidism. The androgen-secreting tumours must be distinguished from adrenal disease and from other virilizing disorders of the ovary (*e.g.*, polycystic ovary, or Stein-Leventhal syndrome) that are associated with failure to menstruate. Other causes of menstrual disorder are pituitary disease, primary disease of the gonads, chronic illness, starvation, emotional upset and a variety of poorly understood disturbances in hormonal balance that have been termed functional.

5. Sterility.—Involuntary failure to reproduce (infertility) occurs in 10% of married couples in most populations that have been studied. In about one-third of the sterile couples, the deficiency is in the female, in another third in the male and in the remaining third in both parties. In a small proportion of the cases no organic cause can be found. Although the progressive increase in world population is regarded as a serious threat on a global scale, the sterile man or woman is plagued by feelings of inadequacy that not only are individual but also are racial and atavistic. Man has always worshiped fertility and from the earliest times sterility has been looked upon as disgraceful: "He whose testicles are crushed or whose male member is cut off shall not enter the assembly of the Lord" (Deut. 23:1). In his diagnostic study the physician tries first to exclude primary developmental or infectious diseases of the gonads, failure of the pituitary gland and severe debilitating diseases of either partner. Next, the number and quality of the sperm are assessed. Finally, an attempt is made to determine the adequacy of the female's Fallopian tubes, the occurrence of ovulation and the presence or absence of various mechanical impediments, *e.g.*, pelvic inflammations, endometriosis and fibromyomas (fibroids) of the uterus. Treatment of the pituitary and of serious systemic disease is followed only very rarely by restoration of fertility. Deficient production of spermatozoa generally cannot be corrected by hormonal treatment. Correction of female infertility is more successful; mechanical problems can sometimes be corrected surgically and it is even possible to induce ovulation by giving human gonadotrophin. The treatment of infertile couples is said to result in pregnancy in 30%–40% of cases; many of these therapeutic successes are undoubtedly due only to the passage of time.

6. Disorders of Sexual Impulse.—Homosexuality (*q.v.*), in which the sexual drive is directed toward members of the same sex, has been observed in all societies, ancient and modern. The cause is almost never organic disease of the gonads, which are generally normal in the homosexual person, as are the secondary sexual structures. Study of body form, hormone secretion and chromosomal complement has yielded normal findings. The usual basis is emotional and usually is rooted in abnormal attachments to or repulsion from one or the other parent, or in unduly early exposure to traumatic sexual stimuli. Homosexuality also may be associated with severe mental disease (*i.e.*, psychosis) or with alcoholism.

Satyriasis and nymphomania, or excessive sexual desire in the male and female respectively, are emotional disorders. Similarly, impotence (inability of the male to perform the sexual act) and frigidity (inability of the female to achieve sexual climax, or orgasm), while characteristic of severe deficiency of gonadal function, are nearly always caused by emotional disturbances. The disorders of sexual impulse are generally resistant to psychiatric treatment and always are refractory to misguided treatment with sex hormones. (N. P. C.)

III. SURGERY IN THE MALE

The purpose of surgery of the male reproductive system is to preserve sexual function. This is a dual objective in that potency (erections and ejaculations) and fertility (a sufficient number of normal spermatozoa) are not synonymous. Erections may be satisfactory, yet spermatozoa may not be produced or delivered. In other instances spermatozoa may be produced but erections may not be satisfactory. Procreation requires both fertility and potency.

Treatment of impotence and infertility may be the task of medicine, psychiatry or surgery. Removal of tumours of the genital organs, draining of abscesses, removal of hopelessly diseased tissue, repair of the results of trauma and correction of congenital defects are exclusively surgical procedures. When the passage of sperm is mechanically blocked, surgery may restore the channel of the vas deferens. It is perhaps strange that, except for circumcision, most operations on the male reproductive system are performed on the prostate gland, which is not essential either to potency or to fertility; when diseased it damages the urinary tract more than the reproductive system.

Some operations on the external genitalia are performed solely to improve appearance. When both testicles are absent because of disease, trauma or congenital defect, artificial testes can be implanted in the scrotum. In hermaphroditism, operations improve

the mental well-being of the patient by reinforcing the appearance of the elected sex. For example, in a hermaphrodite with apparent male organs who is to be female, a large clitoris that has the appearance of a penis may be partially excised and a vagina formed. Some of these operations belong to gynecology.

1. Penis.—In operations on the penis an effort is made to preserve as much of the erectile bodies as possible in order to permit erections.

Circumcision.—This operation is performed most generally on infants shortly after birth but may be performed at any age (*see* CIRCUMCISION). Surgical objectives are to remove excess skin of the prepuce when it cannot be retracted or when it is of such length that it interferes with sexual gratification or urination. Circumcision also reduces the incidence of infection and tumour formation beneath a long foreskin. Unless infection is severe the surgery is carried out in one operation by excising the redundant skin covering the end of the penis. If there is severe infection, the surgery may be performed in two stages: first, a dorsal slit is made to drain the area and later the excess skin is removed. A contraindication to circumcision is the congenital defect in which the anterior urethra has not formed, as in hypospadias. All available skin is required in such operations to form a new urinary channel.

Amputation.—Partial amputation of the penis is indicated for cancer of the penis, a rare form of tumour. When the cancer involves the end of the organ, the line of amputation is one inch proximal to gross signs of tumour. Partial amputation does not impede the power to gain erections. Complete amputation of the penis is indicated for cancer of the penis involving a large part of the organ. A new urethral opening is formed in the perineum and the penis and neighbouring lymph glands are excised to remove structures which may be involved in possible spread of the tumour.

Repair of Lacerated Penis.—In injuries to the penis, such as fractures sustained when the penis is erect, surgery consists of evacuating blood clots and suturing the dislocated and lacerated portions into their normal position. If performed soon after the injury is sustained, this operation is usually successful.

Priapism.—Priapism is prolonged erection of the penis without sexual gratification. Blood vessels of the penis remain engorged and detumescence does not take place. Removal of retained blood by incision and drainage or evacuation with a large surgical needle is one form of treatment. Regardless of treatment, impotence is the usual result.

2. Scrotum.—Few operations are required for abnormalities of the scrotum itself. Most are performed on the scrotal contents. Aside from removal of moles or nevi, the chief indication is elephantiasis. Here the lymphatics are obstructed and the scrotum enlarges to tremendous proportions, reaching to the level of the knees or even to the feet. This condition is common in regions (*e.g.*, India) where filariasis is prevalent; in this disease, small worms obstruct the lymph vessels. Surgery consists of excising most of the mass of the greatly enlarged scrotum.

3. Spermatic Cord.—In surgery of the spermatic cord the aims are to preserve the blood supply to the testicle and the continuity of the vas deferens.

Varicocelectomy.—Dilated veins of the spermatic cord occasionally cause pain. The dilated portions are excised, leaving the arteries to the testicle intact and sufficient veins to drain the testicle.

Correction of Torsion.—When the spermatic cord becomes twisted (torsion of the spermatic cord) through overactivity of the cremaster muscle, which surrounds the cord, the condition must be corrected promptly or gangrene of the testicle results. Operation consists of untwisting the cord and fixing the testicle to the base of the scrotum. The fixation is called orchiopexy. Since torsion is likely to occur in both sides, bilateral orchiopexy is performed even though torsion affects only one side.

Bilateral Vasectomy.—To produce sterility small sections of each vas deferens are excised through small scrotal incisions. This prevents passage of spermatozoa. However, the patient may remain fertile for weeks or months following operation because of spermatozoa stored in the seminal vesicles or prostate. In some rare instances the operation is unsuccessful; the divided vas deferens may grow back together or there may be an accessory vas deferens.

Vasectomy is performed along with operations on the prostate to prevent infection in the prostate from spreading down the vas deferens and causing inflammation of the epididymis (epididymitis). Partial vasectomy may be performed to remove a tumour of the vas deferens; such tumours are rare and usually benign.

Vasovasostomy.—After the vasa have been divided it may be desired to restore fertility. This is accomplished by sewing the divided ends together (vasovasostomy).

4. Cowper's Glands.—Operation on these glands is rarely necessary. Occasionally a tumour develops and excision is required.

5. Tunics of Testicle.—Fibrous layers covering the testicle are minor structures in themselves, but they may give rise to a large swelling of the scrotum by retaining fluid as a result of infection, the entrance of blood into the sac or obscure causes. A collection of clear fluid that transmits light is called a hydrocele; fluid that contains blood and does not transmit light is a hematocele. In a hydrocelectomy, the sac is opened and the edges everted and sutured together behind the testicle. This eliminates the sac. If the wall of the sac is very thick or calcified it is excised, rather than everted.

6. Epididymis.—Since the epididymis serves only as a reservoir for spermatozoa its function is not vital.

Epididymectomy.—Excision of the epididymis is indicated for an infection (most frequently tuberculous) that is not curable with antibacterial drugs. Tumours, which are rare and usually benign, require excision.

Epididymovasostomy.—When the vas deferens is obstructed near its emergence from the epididymis, as from scar tissue following gonorrhea or from congenital defect, sperm cannot pass. In such instances corrective surgery may be performed to restore fertility, provided the testis is normal. An opening is made in the vas deferens and a new communication is formed with the epididymis to short-circuit the obstructed portion of the vas.

7. Testis.—Conservation of a portion of one testis is essential to provide the normal male hormone that gives men a deep voice, male bodily habitat and sexual function. The production of male hormone is distinct from the other function of the testis, *i.e.*, the production of spermatozoa for procreation. The two functions are carried out by different types of cells intermingled in the glandular portion of the testis. When the testis is removed it is useless to preserve the epididymis, since the testis no longer supplies sperm. The chief indication for removing one testis is malignant tumour; both testes are removed to eliminate hormone production in some cases of cancer of the prostate (*see* below).

The testis is exposed through either a scrotal incision or an incision in the inguinal region. If the latter incision is used, the testicle is drawn up by traction on the spermatic cord into the opening in the inguinal region.

Total Orchiectomy.—Removal of the entire testicle is indicated for malignant tumour; testicle tumours usually are malignant. For malignancy, orchiectomy consists of removal of the testis, epididymis and spermatic cord up to the internal inguinal ring where the spermatic cord enters the abdominal cavity. In types of malignant tumour in which X-ray treatment cannot destroy outgrowth of the tumour into the lymphatics, radical orchiectomy may be performed; in this procedure the testis, epididymis, spermatic cord and lymph chains surrounding the blood vessels of the bony pelvis and retroperitoneum are removed.

Bilateral Simple Orchiectomy.—This operation is performed in advanced cancer of the prostate. The purpose is to remove the cells that secrete male hormone, since this hormone (androgen) promotes growth of prostatic cancer. Both testes and epididymides are removed, leaving the spermatic cord, since the sole purpose is to terminate secretion of male hormone. Elimination of the hormone usually suppresses growth and causes recession of cancer of the prostate for a variable time. Other hormonal factors are involved; one is that some male hormone is secreted by

glands other than the testis; *e.g.*, the adrenal.

In subcapsular orchiectomy the glandular tissue of the testis is removed, leaving the capsule of the testis and the epididymis in place for cosmetic effect. The same result is obtained by implanting an artificial (usually plastic) testis in the scrotum to replace a removed testicle.

Partial Orchiectomy.—This operation is indicated when the testis is invaded by an infection that spreads from the epididymis that requires operation, *e.g.*, some cases of tuberculous epididymitis. Tiny portions of the testis occasionally are removed for diagnosis (biopsy) in infertile males. Microscopic examination of the tissue usually gives a clue to the extent and reason for the lack of normal spermatozoa.

Orchiopexy.—This is an operation to correct cryptorchidism, a congenital defect in which the testis does not descend into the scrotum from its site of formation in the lumbar region. When, as is usual, the undescended testicle lies in the inguinal canal, it is possible to isolate the testicle, free and lengthen the spermatic cord and implant the testis in the scrotum. An undescended testis is usually associated with a potential inguinal hernia, which is repaired at the same operation.

8. Prostate.—Surgery of the prostate is performed frequently because of the relatively frequent occurrence of benign enlargement and cancer of the prostate. Prostatic enlargements are most frequent in men over 50 years of age. The enlargement obstructs the outflow of urine through the urethra, which tunnels through the gland. The purpose of this surgery is to relieve urinary obstruction but at the same time to preserve urinary control by avoiding damage to the external urinary sphincter.

Removal of the entire prostate (radical prostatectomy) is the

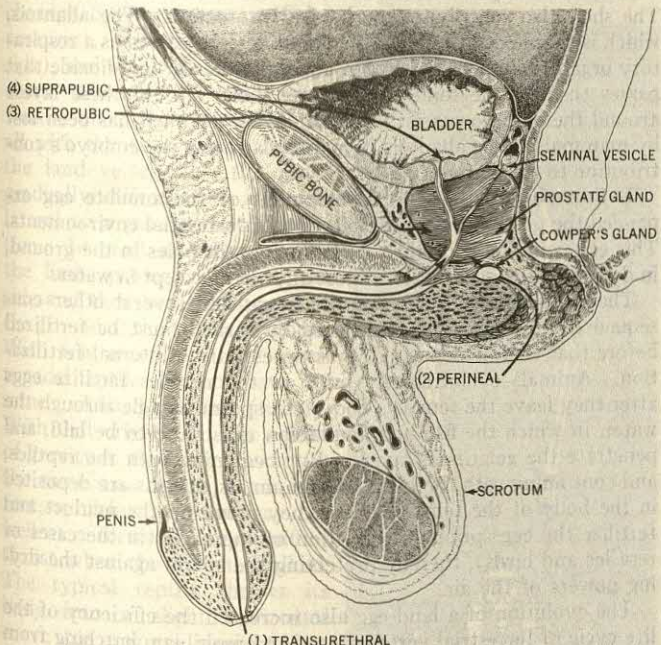

FIG. 5.—VERTICAL SECTION THROUGH PELVIS, SHOWING FOUR SURGICAL APPROACHES TO BLADDER AND PROSTATE GLAND

accepted treatment for cancer if the tumour has not spread beyond the gland. Operations for removing so-called benign prostatic enlargements (conservative prostatectomy) are almost always performed for enlargements of the glands of the urethra and not the prostate. The term prostatectomy is a misnomer when used to describe the removal of the urethral glands because the prostate is not removed and remains in place after the enlarged glands are removed.

Less frequently, a portion of the prostate is removed for stones or for infection (partial prostatectomy). Removal of a thickened outlet of the bladder is sometimes erroneously called a prostatectomy; in this operation, part of the vesical neck is removed. Obstruction of the urethra at the bladder outlet is known as median bar.

Because it is located deep within the bony pelvis, the prostate is difficult to expose by surgery. One of four approaches (*see* fig. 5) is commonly employed, as follows:

Perineal.—The oldest type of incision to expose the prostate is the perineal incision. A curved incision anterior to the rectum is used to expose the posterior surface of the gland by displacing the rectum backward. This operation is suitable for both so-called conservative prostatectomy (removing enlarged periurethral glands from within the prostate) and radical perineal prostatectomy.

Radical perineal prostatectomy consists of removing the prostate for early cancer. After the entire prostate and the seminal vesicles are removed, the neck of the bladder is sewed to the cut end of the urethra.

Suprapubic.—This route provides the most direct approach to the prostate. A low abdominal incision exposes the bladder, which is then opened to gain access to the prostate. For this reason the operation is also termed transvesical prostatectomy. The approach is adaptable only to benign enlargements since the entire prostate cannot be removed through the bladder. The surgeon's finger is introduced far into the urethra, and a line of cleavage makes it possible to shell out the enlarged periurethral glands from within the prostate.

Retropubic.—This approach is likewise through a lower abdominal incision. The bladder is dissected away from behind the pubic bone and the prostate is exposed extraperitoneally. This operation is suitable for both the radical operation for cancer and for removing benign enlargements. In the former, after the prostate and seminal vesicles are removed, the divided neck of the bladder is sutured to the cut end of the urethra. In so-called conservative prostatectomy, after the anterior surface of the gland is exposed retropubically an incision is made through the capsule of the prostate and the enlarged urethral glands are enucleated from within the prostate.

Transurethral.—This approach is made through the urethra without an open surgical incision. This technique makes use of an incandescent lamp, multiple lens optics and high-frequency electrosurgical currents that are capable of making precise cuts of tissue under water. This operation is most useful for removing all types of small enlargement, either within the prostate or at the vesical neck; it is not suitable for radical removal of the entire prostate for cancer.

9. Seminal Vesicles.—Surgery on the seminal vesicles is rarely necessary. Very occasionally these glands, which lie posterior to the prostate, are the site of tumour and require excision (seminal vesiculectomy). Surgery is also occasionally indicated for an infection that is not relieved by antibacterial drugs.

REPTILE, any member of the class Reptilia, including snakes, lizards, crocodiles, alligators, turtles, and the tuatara, among the living forms, and a great many extinct types such as dinosaurs, pterosaurs, and ichthyosaurs.

Intermediate between amphibians and the warm-blooded vertebrates, reptiles may be described as those air-breathing vertebrates practising internal fertilization and having a scaly body covering instead of hair or feathers.

I. EVOLUTIONARY SIGNIFICANCE

Reptiles occupy an evolutionary position between amphibians, on the one hand, and the birds and mammals on the other, the last two classes having evolved from reptilian ancestors. Reptiles first appear in the fossil record of the Carboniferous Period, over 250,000,000 years ago. By the Triassic, about 50,000,000 years later, they began to dominate the terrestrial life of the world and continued that dominance through the Mesozoic Era. Reptiles succeeded in adapting to deserts, swamps, forests, grasslands, rivers, lakes, and even the air and the seas. Coincident with the rise of mammals at the end of the Mesozoic, most of the varied reptilian groups became extinct. (*See* PALEONTOLOGY.)

1. Basic Changes.—The big evolutionary step made by reptiles was the final emancipation from life in water, for until that step was taken vertebrates could not exploit all of the earth's surface. That breakthrough required two basic changes.

The first of these changes took place in the skin. Modern amphibians have naked skins that lack horny scales, hair, or other protective devices. One small amphibian group, the caecilians, has small fishlike scales embedded in the skin, and similar scales occurred in some ancient extinct amphibians. Because of their thinness and position, these amphibian scales are no protection against desiccation, one of the principal hazards of life for all animals, vertebrate or invertebrate. This susceptibility to drying-out forced (and still forces) amphibians to remain in water or in very humid places, thus limiting their exploitation of the terrestrial environment. Reptiles evolved a different type of scale consisting of keratin (or horn) deposited in the outermost layer of the skin (fig. 1). This type of scale was in a position and of a thickness to prevent desiccation.

The second basic change made by the reptiles was the development of what is called the amniote egg. The eggs of their evolutionary predecessors, the amphibians, are surrounded only by several layers of gelatinous material after they are laid. Sperm penetrate the gelatinous envelopes and fertilize the eggs. Embryos develop still surrounded by the gelatinous layers until the young hatch. Amphibian eggs must be laid in water or in places where the air is saturated with moisture, for the gelatinous coverings cannot protect them from desiccation. This exigency requires all amphibians to return to water for breeding and limits the kinds of environments in which the adults can live.

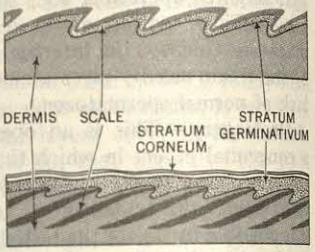

FIG. 1.—COMPARISON OF (TOP) REPTILIAN AND (BOTTOM) AMPHIBIAN SKINS SHOWING THE DIFFERENCE IN POSITION OF THE SCALES

The embryo of a reptile soon develops a thin sac, the amnion, that envelops the embryo and becomes filled with a watery fluid (fig. 2), the entire structure serving to protect the embryo from desiccation and mechanical injury. A parchmentlike shell produced by the female parent surrounds the amnion, but between the shell and the amnion a second sac, the allantois, becomes inserted. The shell also contributes mechanical protection. The allantois, which is supplied with many fine blood vessels, serves as a respiratory organ to absorb the oxygen and emit the carbon dioxide that passes through the somewhat porous shell. All of these layers around the embryo persist in birds. Only the shell has been lost by mammals. The allantois in mammals forms the embryo's contribution to the placenta.

2. Consequences.—The development of the amniote egg expanded the possibilities of exploitation of terrestrial environments. This egg could be laid under rocks or logs, in holes in the ground, in deserts or forests, in fact, almost anywhere except in water.

The development of the reptilian egg had several other consequences. An egg that is enclosed by a shell must be fertilized before that shell is deposited, thus necessitating internal fertilization. Animals evolutionarily prior to the reptiles fertilize eggs after they leave the female's body; the sperm wriggle through the water, in which the fish and amphibian eggs have to be laid, and penetrate the gelatinous layers. But beginning with the reptiles, and continuing with the birds and mammals, sperms are deposited in the body of the female, where they move up the oviduct and fertilize the eggs prior to deposition of the shell (in the cases of reptiles and birds), thereby protecting the sperm against the drying powers of the air.

The evolution of a land egg also increased the efficiency of the life cycle of terrestrial vertebrates. An amphibian, hatching from an aquatic egg, must develop and grow in water in a larval form, the tadpole. Because the supply of yolk—the sole source of food for the developing embryo—in an amphibian's egg is small, the length of time between fertilization of the egg and hatching of the tadpole is very short. In that short interval, and with that small amount of raw material, the amphibian embryo cannot develop all the organs needed for terrestrial life; it can only develop a nervous system, with sense organs, and digestive, circulatory, and excretory systems. It has no bony skeleton or limbs, without which support and locomotion

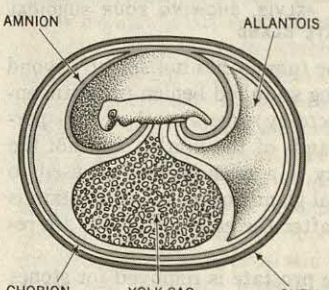

FIG. 2.—AMNIOTE EGG

on land are impossible. The tadpole differs from the adult amphibian in anatomy, behaviour, and environmental needs because of its aquatic existence; it therefore must undergo a radical and physiologically dangerous change called metamorphosis between its aquatic and terrestrial lives.

The reptile, on the other hand, does not lead a double life. From the time of fertilization onward, the history of a reptile is one of development and growth of adult structures adapted for a terrestrial life. It need not develop gills or a lateral line system, which are needed by the aquatic tadpole and which must be resorbed and reworked into other structures later. This important change in the type of development was made possible by a great increase in the amount of yolk in the reptilian egg.

The large amount of yolk also permitted the lengthening of the embryonic period, in turn allowing the development of all structures necessary for successful existence on land. When a reptile hatches, it is ready to carry out all of the activities of the adult, and in the same environment and manner. The only exception is the inability of juvenile reptiles to reproduce; the sex organs still require time to mature.

After reptiles acquired scaly protection for their skin and an egg that did not have to be laid in water, they were free to move over most of the earth's surface. That freedom set the stage for the evolution of the many varied types of reptiles and, ultimately, the evolution of birds and mammals.

II. NATURAL HISTORY

A. Locomotion

1. Walking and Crawling.—The majority of reptilian orders are and have been quadrupedal. Turtles (Chelonia), lizards (Squamata), crocodiles (Crocodilia), rhynchocephalians (Rhynchocephalia), pelycosaurs (Pelycosauria), therapsids (Therapsida), and many of the ornithischian dinosaurs (Ornithischia) walked on all fours, though not all with the same gaits. Among the land vertebrates, the limbs gradually shifted from a purely lateral to a purely ventral position. In most amphibian types the limbs projected out to the side and then bent downward to the ground at the knee and elbow. With few exceptions, the quadrupedal reptiles had and have the same awkward position (fig. 3). With that orientation, the centre of gravity of the body was not in the same axis as the hands and feet, resulting in a sideways as well as a forward component of thrust when the animal walked. The typical reptile throws its body into a slight horizontal curve to progress straight forward. In mammals the limbs are directly underneath the body; the centre of gravity is in the axis of the limbs; and all of the thrust of the limbs is directed forward. The latter position and type of motion are more efficient. The lateral orientation of the limbs in amphibians and reptiles also makes it more difficult to raise the body off the ground.

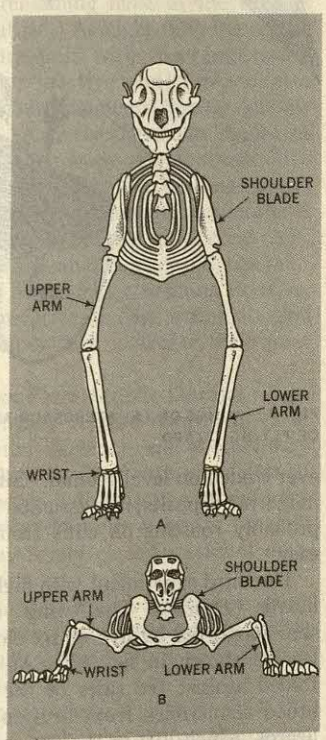

FIG. 3.—COMPARISON OF LIMB ORIENTATION IN (A) MAMMAL AND (B) REPTILE

Despite the awkwardness of the orientation of their limbs, some reptiles are (and many extinct forms probably were) capable of moderate speeds. Crocodilians, for example, raise their bodies off the ground and make short, fast rushes. Short-bodied lizards are also often fast, though for short distances. Longer-bodied lizards have greater difficulty in raising their bodies, and some cannot. The last usually have short legs and proceed in a serpentine fashion, with the body, thrown in horizontal curves, doing more or less of the work depending on whether the legs are shorter or longer, respectively.

A snake (or a virtually limbless lizard) moves by pushing backward against rocks, sticks, or any relatively fixed point—a lump of earth or a small depression in uneven ground will do—with the rear surface of the horizontal curves of its body. Each joint of the body passes through the same curves, pressing against the same object and thrusting the fore part of the body forward. Even arboreal snakes use this method of locomotion, pushing against branches as they extend their bodies across gaps to new perches. On very smooth surfaces, such as glass or a wide board covered with a thick layer of fine dust, this horizontal undulatory movement, as it is called, does not work. Instead the snake remains in one place while its body executes "swimming" motions.

Heavy-bodied snakes such as pythons and certain rattlesnakes can move forward without throwing their bodies into curves. This rectilinear movement depends on the ability of snakes to stretch or contract their bodies in the longitudinal axis. By raising a part of its belly, stretching that part forward, lowering it to the ground, and repeating the process alternately with other parts of the body, a heavy snake moves forward smoothly in a straight line.

Returning to the more general type of reptilian locomotion, some modern lizards have adopted semibipedal locomotion. Unrelated lizards, such as the collared lizard (*Crotaphytus collaris*) of the United States and the frilled lizard (*Chlamydosaurus kingi*) of Australia, show the early stages of bipedalism, a phenomenon widespread among the dinosaurs and therefore important in their history. These lizards run on their long hind legs with the forward parts of their bodies at an angle of about 60° off the horizontal when they travel at top speed, which, though fast for a reptile, is still much slower than that of a running man. A long tail held off the ground acts as a counterbalance.

Presumably, bipedalism among the dinosaurs began as it did among modern lizards, as an occasional means of obtaining bursts of speed. Because the centre of gravity is in front of the hips, modern bipedal lizards must move forward continuously in order to maintain a semierect posture; they can stand still in that position only for very short periods. At the culmination of this evolutionary trend, a bipedal dinosaur probably remained semierect habitually and dropped to all fours only occasionally. This inference is based on the observations that the front limbs of these dinosaurs became very short and weak and were probably incapable of supporting much weight for any length of time. Furthermore, since the tails of bipedal dinosaurs were on the whole relatively heavier than those of the lizards, thus shifting the centre of gravity closer to the hips, it probably required less effort for the dinosaurs to remain erect. (*See* also Dinosaur.)

The awkward sideways orientation of the limbs forces bipedal lizards to swing each leg outward as it is brought forward and to push the body sideways and forward when each leg thrusts backward against the ground. Bipedal dinosaurs eliminated this inefficient rocking motion, for during the course of evolution their hind limbs were rotated forward so that they were directly under their bodies. Thus they delivered their full force in the forward direction. So successful was this mode of locomotion that dinosaurs utilizing it dominated terrestrial life for millions of years.

2. Clinging and Climbing.—Considering the range of habitats occupied by the extinct reptilian orders, one may safely assume that some were arboreal. But animals having that mode of life are not likely to be preserved as fossils. Hence our knowledge of arboreal adaptations in reptiles is limited to those of contemporary groups.

Associated with arboreal life are groups of anatomical features mainly concerned with clinging. The commonest clinging structures in vertebrates are claws; they seem to be the only arboreal adaptations of some lizards, for example, the common iguana (*Iguana iguana*). Similar structures appear in many lizards of the family Gekkonidae, in the anoles (*Anolis*) of the family Iguanidae, and in some skinks of the family Scincidae. The pads consist of wide plates or scales under the fingers and toes. The outer layer of each plate is composed of innumerable tiny hooks

formed by the free, bent tips of cells. These minute hooks catch in the slightest irregularities and enable geckos to run up apparently smooth walls and even upside down on plaster ceilings. Since the hooklike cells are bent downward and to the rear, to disengage them a gecko curls its toes upward. Thus in walking or running up a tree or wall, a gecko must curl and uncurl its toes at every step.

The giant Solomon Islands skink (*Corucia*), true chameleons (Chamaeleontidae), arboreal vipers, and pythons use prehensile tails—that is, tails capable of supporting most of the weight of the animal or used habitually for grasping—for clinging to their aerial supports. For this purpose, however, true chameleons rely mainly on a tonglike arrangement of their digits, which are united into two opposed bundles on each foot—three on the inside and two on the outside of the front foot, and two on the inside and three on the outside of the hind foot.

Although all snakes can curl their tails around objects, prehensile tails are confined to the heavy-bodied types mentioned above. Other parts of the snake's body may be used to supplement the tail in grasping branches, as when a python moves through trees, but the most important assist to the tail is the even distribution of weight of the body on each side of a branch.

At the opposite pole from the thick-bodied vipers and pythons are the excessively slender vine snakes of several genera of the family Colubridae. Any of these slender snakes is capable of extending half of its body length in a horizontal plane without support, and usually does so habitually in bridging the gap between branches. Most snakes can reach across an open space, but all except these vine snakes can extend only a short length of the body, and that portion invariably sags like a cable. The vine snakes bridge an open space like an I-beam. This ability is based partly on a reduced body weight, which follows from the body form, and partly on deepened and strengthened vertebrae.

3. Swimming.—In water, of course, neither bipedal nor quadrupedal locomotion is very effective. Aquatic reptiles, with few exceptions, use the same means of propulsion as do fishes and whales, that is, powerful beats of the tail. Crocodilians and aquatic lizards such as some monitors (Varanidae) lash their tails from side to side while the limbs are held against the body. This same method was used by the ancient mesosaurs (Mesosauria) and ichthyosaurs (Ichthyosauria). The marine ichthyosaurs, which were the reptilian counterpart of the porpoises, may have used their very short limbs for steering.

This fishlike method of swimming requires a flexible body and at least a moderately long tail. Turtles, encased in armour and having what is probably the most inflexible body among vertebrates, cannot use the common swimming technique. Instead they propel themselves by using their feet as paddles—the hind feet, which have webbed toes, in the case of fresh-water turtles, and the fore feet, which are modified into large paddles, in the case of marine turtles.

The extinct marine plesiosaurs (suborder Plesiosauria), with their short bodies and tails and their large paddlelike limbs, swam the way marine turtles do, although they may have used their hind limbs for more than just steering. Both pelvic and pectoral (shoulder) girdles were modified in the plesiosaurs into structures having small upper portions and very large lower portions. As the upper element, especially that of the pelvic girdle, has the important function of transferring the weight of the body to the limbs, it is likely that the limbs of plesiosaurs could not support the body weight on land and that the plesiosaurs never came out of water. The much-enlarged lower parts of the girdles served for the attachment of the strong musculature operating the paddles.

Most plesiosaurs had moderately long necks, and some had very long necks. By moving toward their prey (probably fishes) with the neck curved, they probably could strike suddenly forward or sideways to catch their agile prey. The heavy trunk would provide the inertia against which the head and neck could move, thus preventing a significant backward shift of the animal as the head and neck shot forward.

A contemporary group of marine reptiles, the sea snakes (Hydrophidae), show the same adaptation. Though they swim with a fishlike or, rather, an eellike undulation of the body, the sea snakes have relatively small heads, slender necks, and very heavy-bodied mid and rear sections. If a sea snake had the body proportions of an ordinary terrestrial snake, each segment of the body would have roughly the same mass. If such a snake struck at a fish with the forward third of its body, about half of the forward motion would be lost as the rear of the body (by reaction) was thrust backward. But with most of the body mass concentrated in the second half of the animal, almost all of the force of the strike is used to drive the head forward.

4. Flying.—Three groups of reptiles have experimented with flight. Thecodontia, a group of Archosauria (the so-called ruling reptiles, which included dinosaurs and crocodilians), became almost unbelievably successful at this means of locomotion, and almost overnight (as these things are measured in geological time) evolved into birds.

A second group of archosaurs, the Pterosauria, developed wings that were supported along the front margin by the arm and an extremely elongated finger (fig. 4A). The pterosaur wing was made of skin, and since it lacked both internal supports and feathers it probably lacked the flexibility or durability of a bird wing. Flight of the pterosaurs presumably amounted to soaring and gliding. What is not understood is how pterosaurs moved about when not flying and how they managed to take off if they

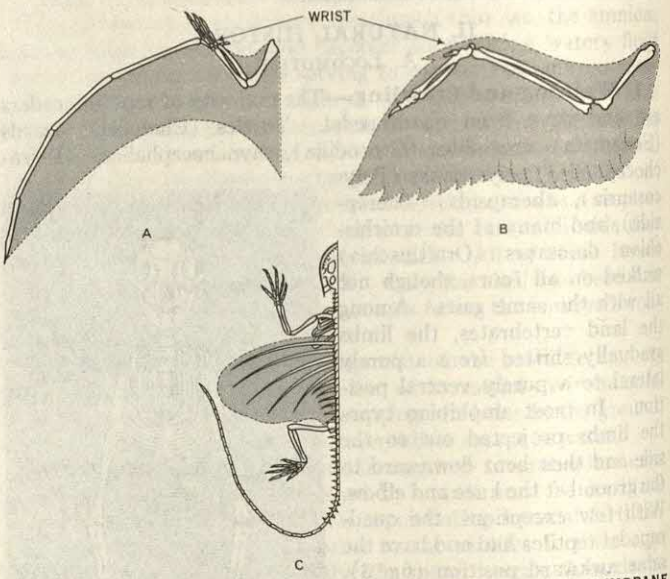

FIG. 4.—WINGS OF (A) PTEROSAUR AND (B) BIRD. (C) GLIDING MEMBRANE OF FLYING LIZARD

ever landed on level ground. Since most remains have been found in marine deposits, it is assumed that they lived along ocean shores, probably roosting on cliffs from which takeoff would have been easy.

The third experiment with flight was made by a group of modern lizards (*Draco*). The "wing" of these small lizards consists of skin supported by five or six elongated ribs between the arm and leg, as shown in fig. 4C. At rest the ribs and the wings are folded against the sides of the body. In flight the wings form broad semicircles from arm to leg on each side. These flying lizards, which live in the forested country of Southeast Asia and the East Indies, are capable only of gliding. Like flying squirrels, which they resemble in the position of the flight membrane, a flying lizard launches itself into the air and glides toward another tree, descending slowly and turning upward sharply just before lighting on the new perch. Since the arms and legs are not modified, this lizard is capable of scampering up and down tree trunks like any strictly arboreal lizard.

B. Thermal Relationships

Reptiles are often described as being cold-blooded, which is not always true. Their body temperatures are not always low, but these animals have no internal mechanism for regulating

body temperature and thus approximate closely the temperature of their surroundings. This condition is termed poikilothermy. Mammals and birds maintain their relatively high body temperatures at a relatively constant level by physiological means that are independent of the external environment, a condition called homoiothermy (*see* ANIMAL HEAT). When the body temperature of a dog or a man falls below the normal range, he begins to shiver, blood vessels in the skin contract, muscular activity generates heat, and the contraction of the superficial blood vessels, by reducing the volume of blood flow at the surface, reduces heat loss by radiation. By contrast, a reptile, when its body temperature falls below the optimum, must move to some portion of the environment having a higher temperature; in less than optimal temperatures its activity drops, its movements become sluggish, its heartbeat is slowed, and its rate of breathing drops. In short, it becomes incapable of normal activities required for growth, reproduction, and survival.

High temperatures also are hazardous for animals. Mammals and birds have some physiological means of cooling their bodies (*e.g.*, panting and sweating, expansion of superficial blood vessels), but a reptile must move away from a spot in which the temperature is too high or perish very quickly. It may need only to move to the shady side of a bush, or it may retreat into a burrow or move into water.

By such movements reptiles seek out those portions of their environments in which they can maintain their bodies near the optimal temperatures, the level at which each species carries out its bodily functions at maximum efficiency. Characteristically, a reptile that normally is active by day moves into the morning sun and basks until its body temperature reaches the optimum. It then begins to forage for food, momentarily moving into places that are too hot or too cold but remaining most of the time in places close to the optimal temperature. As night falls the reptile seeks shelter; its body temperature falls with the temperature of the environment; and it remains inactive until temperatures rise the next morning. In certain environments having low air temperatures but strong sunlight (*e.g.*, the Peruvian Andes at about 14,000 ft.) reptiles can raise their body temperatures 30°–40° F (17°–22° C) above the air temperature by basking.

If, because of cloudy weather, the environmental temperatures do not rise to the optimal level of a given species for several days, the reptile operates at less than maximum efficiency (if the temperatures are high enough for any activity) or remains inactive. It is this kind of physiological inefficiency that mammals and birds have overcome by internal temperature control to their great ecological advantage.

Each group of reptiles has its own characteristic thermal range. One genus of lizards, for example, may require temperatures of 85°–90° F (29°–32° C) for maximum efficiency, and another may require 75°–80° F (24°–27° C). As a result of such physiological differences, lizards of these two groups will be active at different times of the day or occupy slightly different habitats (shaded versus exposed situations), and may rarely come in contact even though they live in the same general area.

In general the normal activity temperatures of reptiles are lower than those of most mammals; however, a few sun-loving (heliothermic) lizards (*e.g.*, the greater earless lizard, *Holbrookia texana*, of southwestern United States) have average activity temperatures above 100° F (38° C), several degrees higher than the average human body temperature. Such high temperatures are exceptional, and the majority of lizards have normal activity temperatures in the 80°–95° F (27°–35° C) range.

C. DEFENSES

1. Avoidance.—This, the commonest form of defense in the animal kingdom, is also the commonest in reptiles. At the first recognition of danger, most snakes and lizards crawl or scamper away into the undergrowth, whereas turtles and crocodilians plunge into water and sink out of sight. But should the danger arise so suddenly and so close at hand that flight may be hazardous, other expedients are adopted.

2. Noise.—Crocodiles, some lizards, turtles, and some snakes hiss loudly when confronted by an enemy. The most spectacular use of sound in warning or threatening behaviour is made by rattlesnakes. The buzzing of the tail rattle is a sound instantly recognized, even when heard for the first time by anyone who has read about these snakes. (A few snakes without rattles [*e.g.*, the fox snake, *Elaphe vulpina*, of the United States] vibrate the ends of their tails rapidly, and if, as often happens, the tail hits dry leaves, it makes a sound deceptively like the rattle of a rattlesnake; but this use of sound is fortuitous.)

3. Change in Body Form.—Change in body form is relatively common in snakes and usually involves spreading the neck, as in cobras (family Elapidae), or the whole body, as in the harmless hognose snakes (*Heterodon*) and DeKay's snake (*Storeria dekayi*) of the United States. Some snakes inflate the forward parts of their bodies; inflation is one of the defensive actions of the large South American tree snake *Spilotes* and of the African boomslang (*Dispholidus*).

4. Posturing.—Threatening postures may be assumed by snakes at the same time that they change their body form. A cobra raises the fore part of its body and spreads its hood when endangered. The typical defensive posture of a viper is with the body coiled and the neck held in an S curve, the head poised to strike.

Some lizards flatten their bodies, puff out their throats, and turn broadside to the enemy. The helmeted iguanids (*Corythophanes*) of Central America and the chameleons of Africa, both arboreal groups, increase their apparent size in this way when approached by snakes. Other lizards face their enemies before displaying. The Australian bearded lizard (*Amphibolurus barbatus*) spreads its throat downward and outward. The Australian frilled lizard (*Chlamydosaurus kingi*) suddenly raises a wide membrane or frill, extending backward about 2½ in. from the throat. The span of the frill in *Chlamydosaurus* may be 7 in. in a lizard having a head and body length of 8 in. As this lizard spreads the frill, it opens its mouth. Many lizards and snakes open their mouths when threatened, but do not strike. A common African lizard, *Agama atricollis*, faces an enemy with head held high and its mouth open to show the brilliant orange interior.

5. Display of Colour.—Display of colour in the case of *Agama atricollis* may not be part of a threatening mechanism, but it is in the instances of certain red- or yellow-bellied snakes that turn over or curl their tails up, exposing the brightly coloured undersurface. This behaviour, known in harmless (*e.g.*, the American ring-necked snake, *Diadophis*) as well as venomous snakes (*e.g.*, the coral snake, *Micrurus frontalis*), is displayed only by snakes having red, orange, or yellow undersides. These colours must have some significance, as yet not fully understood, to predacious animals, for they are the common colours in insects having warning coloration. (*See* also COLORATION, BIOLOGICAL.)

6. Striking and Biting.—If a threatening posture does not succeed in driving off the enemy, many reptiles become more aggressive. Some snakes (*e.g.*, DeKay's snake) strike, but with their mouths closed. Others (*e.g.*, the hognose snakes) strike with their mouths open, but do not bite. Still others strike and bite viciously. Among the nonvenomous snakes of North America, few are as quick to bite as the water snakes (*Natrix*). The sole danger from the bites of these snakes is infection of the wound.

Most of the dangerously venomous snakes (vipers, pit vipers, and cobras) bite in self-defense. Vipers and pit vipers usually strike from a horizontally coiled posture. From this position the head can be shot forward, stab the enemy, and be as rapidly pulled back in readiness for the next strike. It is not necessary for a pit viper to lunge forward in order to inject its fangs; many a careless snake handler has been bitten by a rattlesnake that simply twisted its neck and grabbed the hand that held it. But when free the characteristic defensive strike of a viper is a quick horizontal lunge and withdrawal. From the typical raised posture a cobra sweeps its head forward and downward to bite. To strike again it raises its head and neck once more. These aggressive, defensive movements of cobras are slower than those of pit vipers. (For treatment of poisonous snakebite, *see* SNAKE.)

Many lizards, regardless of family and size, bite in defense.

The largest of the geckos, *Gekko gecko* of Southeast Asia, an animal 10 to 14 in. long, will bite with a bulldoglike grip if sufficiently threatened. Although small lizards have a bite effective against only the smallest predators, a large monitor lizard (*Varanus*) can inflict a painful wound with its large teeth and strong jaws. Some turtles, particularly the soft-shelled turtles (*Trionyx*), bite frequently, vigorously, and effectively.

7. Spitting.—The spitting of venom by certain African cobras, the ringhals (*Hemachatus haemachatus*) and the black-necked cobra (*Naja nigricollis*), is a purely defensive act directed against large enemies. A fine stream of venom is forced out of each fang, which, instead of having a straight canal ending in a long opening near the tip as in most cobras, has a canal that turns sharply forward to a small round opening on the front surface well away from the tip. At the moment of ejection the mouth is opened slightly, and venom is forced out of the fangs by contraction of the muscle enveloping the poison gland. At least one observer noted that a cobra hissed sharply each time it spat, suggesting that part of the propulsion of the venom comes from air forced out of the lung by the body musculature. Usually a spitting cobra raises its head and fore part of its body in the characteristic cobra defensive posture prior to spitting, but venom can be ejected from any position. The venom is aimed high and usually strikes the victim in the face. The effect on the skin is negligible. The eyes, however, may be severely damaged, and blindness can result unless the venom is washed out quickly. One explanation of the function and evolution of spitting holds that the large herbivores of Africa form a group of enemies because of their weight and sharp hooves and that it has been advantageous to these cobras to be able to warn off these herbivores at a distance (up to six feet). A similar explanation has been suggested for the evolution of the rattle of rattlesnakes.

8. Use of Tails.—A few lizards, representing different families, have in common thick tails covered by large, hard, spiny scales. Such a tail swung vigorously from side to side is an effective defense against snakes, especially when the head and body of the lizard are in a burrow or wedged between rocks.

Lizards' tails are useful in defense in another way. When captured, many lizards voluntarily shed their tails, which wriggle violently, temporarily confusing the predator and allowing the lizard to escape. Each vertebra of the tails of lizards having this capacity has a fracture line and can be split on that line when tail muscles contract violently. Simultaneous stimulation of the nerves in the severed portion keeps it twitching for a few seconds after separation. Usually the tail is broken in only one place, but a few lizards, particularly the so-called glass snakes (*Ophisaurus*), break their tails into several pieces. The stump heals quickly and a new tail is grown, though often not so long as it was originally and often with simpler scales.

Snakes, turtles, and crocodiles may have their tails bitten off by predators, but they cannot break them voluntarily or regenerate them. Some snakes use their tails in diversionary tactics by raising them and moving them slowly. Species with this habit commonly have thick, blunt, brightly coloured (often red) tails as, for example, that of the Oriental pipe snake, *Cylindrophis*. The movement and form of the tail may be said to mimic the head and thus confuse an enemy. However questionable that suggestion may be, a moving part of the body attracts more attention than an immobile part, and the predator's attention is probably drawn from the head to the less vital tail. The small African python *Calabaria* and the Oriental venomous snake *Maticora* wave their tails in the air as they move slowly away from a threat.

9. Balling.—Many snakes, harmless (*e.g.*, the North American ring-necked snakes and the African *Calabaria*) or venomous (*e.g.*, the coral snakes, *Micrurus*, and the Oriental *Maticora*), attempt to hide their heads under coils of their bodies. The body may be coiled loosely, as it is in most species with this habit, or tightly so that it forms a compact ball with the head in the centre. Balling, as the latter habit is called, is a characteristic response of *Calabaria* and another African python, *Python regius*.

The African armadillo lizard (*Cordylus cataphractus*), a species having heavy scales on its head and hard spiny scales covering its body and tail, rolls on its back and grasps its tail in its mouth. It thus presents a ring of hard spines to a would-be predator.

10. Odours.—Some reptiles use musk-secreting glands when other defensive measures fail. The water snakes (*Natrix*), the garter snakes (*Thamnophis*), the alligator lizards (*Gerrhonotus*), and the musk turtles (*Sternotherus*) emit a foul-smelling substance from anal glands.

11. Combining Elements.—All of the defensive tactics mentioned so far must be considered a series of responses, not all of which are elicited at once or during the course of each instance of danger. Not all species have the same set of tactics, but each usually has more than one response. Which tactic is used depends on the imminence of danger; enemies evoke one response when at a distance, another when they are close. The change from one response to another as the intensity of the threat increases is illustrated by the behaviour of the North American hognose snakes. If approached by a man, a hognose snake spreads its head (by spreading the hinges of its jaws) and neck and flattens its body. If the man comes closer, the snake hisses and strikes, but does not bite. Should the man tap the snake with a stick or his foot, the snake goes through a series of writhing convulsions, finally rolling over on its back as though dead, with its tongue hanging limply out of its mouth. The performance can be interrupted at any point by the removal of the threat, but as long as the danger appears to increase, each successive response is evoked.

Many reptiles also exhibit passive defenses, among which camouflage involving form and colour is common. Many arboreal snakes and lizards (*e.g.*, chameleons) are green; some of the green snakes (*e.g.*, the vine snakes of South America, *Oxybelis*, and of southern Asia, *Dryophis*) are excessively slender, resembling plants common in their habitat. Lizards of semiarid and rocky country frequently are pale in colour and blotched in pebble fashion, *e.g.*, the leopard lizard (*Crotaphytus wislizeni*) of southwestern United States.

Mimicry of dangerous species by harmless snakes is another passive defense, but one whose validity is challenged by some biologists. The venomous coral snakes (*Micrurus*) of the Western Hemisphere are ringed with bright red, yellow, and black. A series of relatively harmless snakes, such as *Erythrolamprus* and *Anilius* of South America and the scarlet king snake, *Lampropeltis doliata*, of southeastern United States, have similar colours and patterns that may confer some protection against predators.

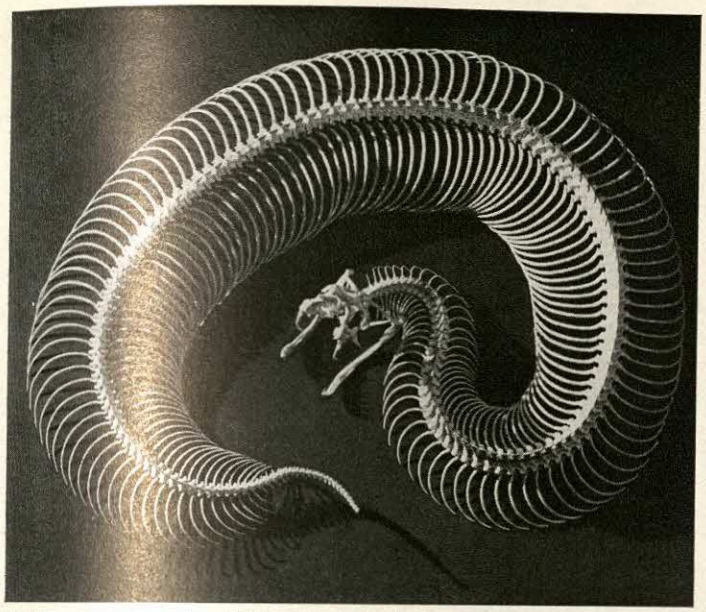
III. FORM AND FUNCTION

A. Diet and Feeding Mechanisms

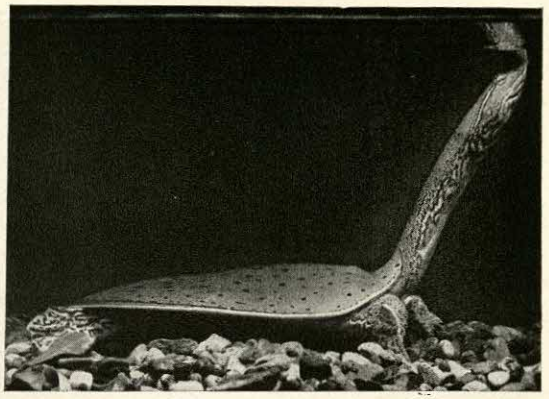
1. Diet.—With few exceptions, modern reptiles feed on some form of animal life: insects, mollusks, birds, frogs, mammals, fishes, or other reptiles. Land tortoises are vegetarians, eating leaves, grass, and in some cases even cactus. The big green iguana (*Iguana iguana*) of Central and South America, its relative the chuckwalla (*Sauromalus obesus*) of southwestern United States and northern Mexico, and the spiny-tailed agamids (*Uromastix*) of North Africa and southwestern Asia are examples of the few herbivorous lizards. The marine iguana (*Amblyrhynchus cristatus*) of the Galapagos Islands dives into the sea to pull up its seaweed food.

The majority of carnivorous reptiles have nonspecialized diets, feeding on a variety of animals. Small- to medium-sized lizards (*e.g.*, the eastern fence lizard, *Sceloporus undulatus*, of the United States and the sand lizard, *Lacerta agilis*, of England and Europe) usually eat many kinds of insects, spiders, snails, and other invertebrates. The common water snake (*Natrix sipedon*) of the United States feeds on fishes, tadpoles, frogs, salamanders, and crayfish; the coachwhip snake (*Masticophis flagellum*) feeds on rodents, birds, lizards, and snakes. Aquatic carnivorous turtles usually eat snails, earthworms, crayfish, frogs, and fishes. Crocodiles prey on fishes, frogs, turtles, birds, mammals, and even insects.

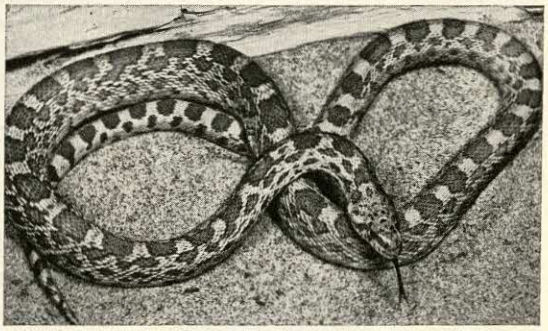
In general the smaller the reptile, the smaller its prey. This principle operates not only in comparing different species, but also within species. Newly hatched alligators feed almost exclusively on insects and only begin to prey on small vertebrates such as frogs and small fishes as they grow larger. Wading birds, turtles, muskrats, raccoons, and other mammals are attacked by



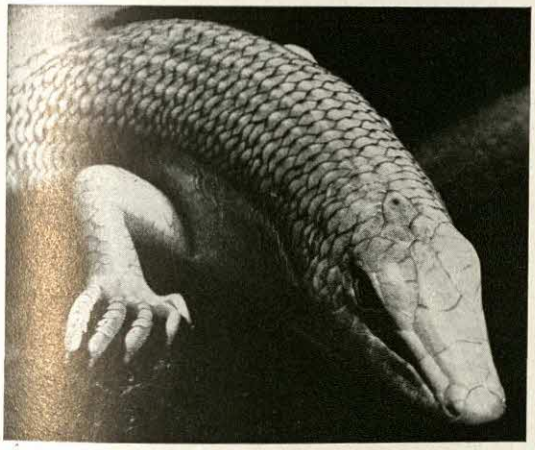
Skeleton of a gaboon viper (*Bitis gabonica*), showing arrangement of vertebrae and ribs. The sharp fangs of this snake—which is poisonous—may be seen in the upper jaw



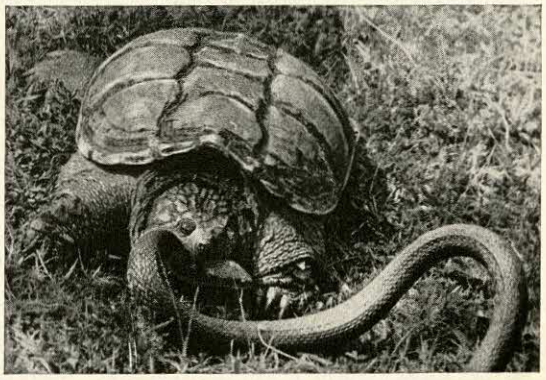
Spiny softshell turtle (*Trionyx* species) with its neck stretched out to bring its nostrils above the water. All reptiles are air breathing and have lungs



Bull snake (*Pituophis catenifer* subspecies) with its forked tongue extended. The flicking of the tongue is a response to odour or vibration. When retracted, the tongue touches Jacobson's organ, a chemical receptor in the roof of the mouth

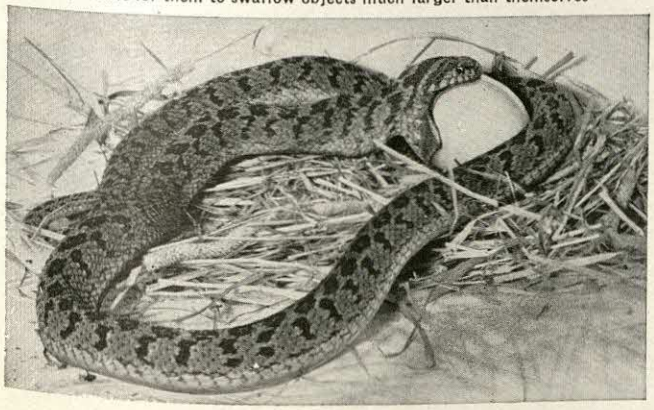


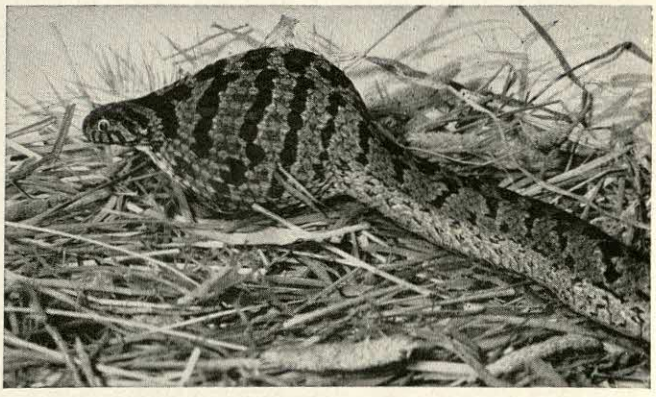
Close-up of the head of a sand skink (*Scincus philbyi*), showing the scaly epidermis characteristic of reptiles. The scales are composed of keratin, a hornlike tissue, which prevents drying of the skin, thus making it possible for reptiles to adapt themselves to nonaquatic life



Snapping turtle (*Chelydra serpentina*) eating a water snake (*Natrix* species). The great majority of reptiles are carnivorous, feeding on a variety of animal life

Two photos showing the egg-eating snake of Africa (*Dasypeltis scaber*) enjoying its favourite meal. The joints and hinging of the lower jaw in snakes make it possible for them to swallow objects much larger than themselves





BODY STRUCTURE AND DIET OF REPTILES

REPTILE

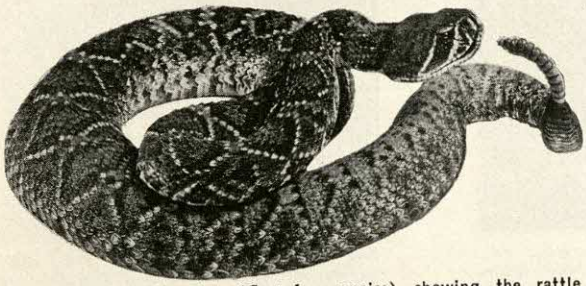
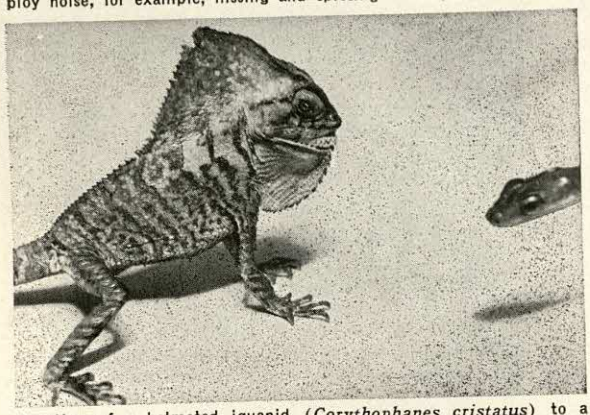
Asiatic toad-headed agamid (*Phrynocephalus mystaceus*) in defense posture. The large, brightly-coloured flaps are attached to the corners of the mouth. When extended, as shown, the mouth appears much larger and wider and is thus more formidable to enemies



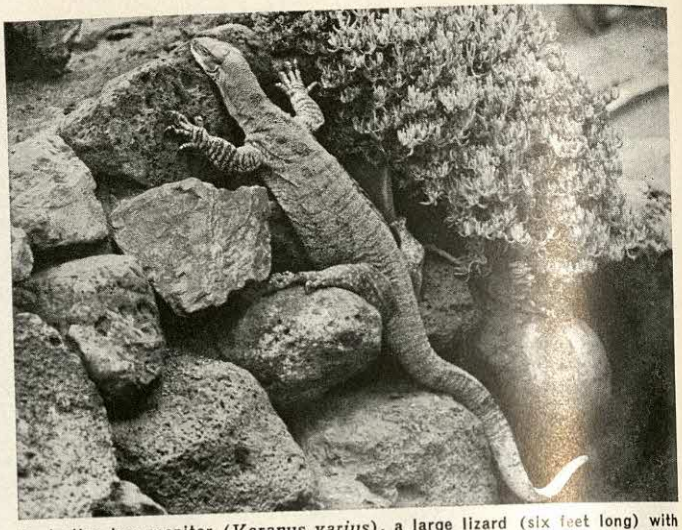
Diamondback rattlesnake (*Crotalus* species) showing the rattle which is used as a warning or threatening device. Other snakes employ noise, for example, hissing and spitting sounds, as a defense



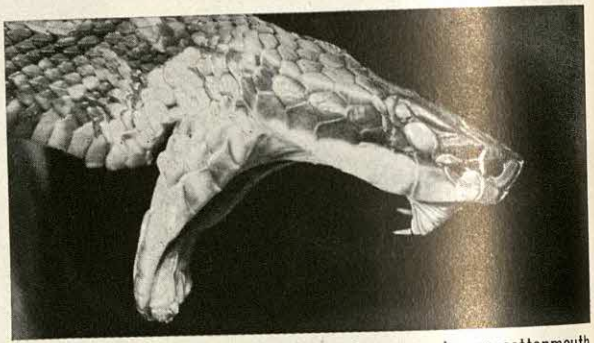
Reaction of a helmeted iguanid (*Corythophanes cristatus*) to a snake. The dewlap is extended and the body tensed to jump. This lizard will run on its hind legs when frightened

DEFENSE AND REACTION TO DANGER

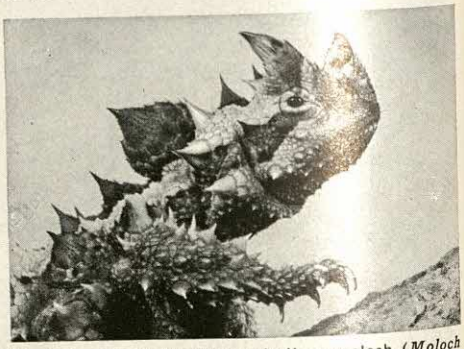
Two male green anoles (*Anolis carolinensis*) preparing to fight. The one on the left is in a defensive position with the crest raised, dewlap extended, the dark spot behind the eye displayed and body widened and flattened



Australian lace monitor (*Varanus varius*), a large lizard (six feet long) with a heavy tail which can be an effective weapon when swung vigorously. The monitors also have strong jaws and large teeth



Detail of the mouth and fangs of a water moccasin, or cottonmouth (*Agkistrodon* [*Ancistrodon*] *piscivorus*), a poisonous snake that injects its venom into its victims through a duct in the fangs



Head of an Australian thorny devil, or moloch (*Moloch horridus*), an example of passive defense through body form. Despite its appearance, the moloch is inoffensive

An Indian cobra (*Naja naja*) with its hood extended. Spreading or inflation of all or part of the body in defense is common among many types of reptiles

BY COURTESY OF (TOP RIGHT) AUSTRALIAN NEWS AND INFORMATION BUREAU, (SECOND LEFT) U.S. FISH & WILDLIFE SERVICE; PHOTOGRAPHS, (TOP LEFT) R. MERTENS, (SECOND RIGHT) HUGH SPENCER, (THIRD LEFT) D. DWIGHT DAVIS, (THIRD RIGHT) JOHN WARHAM, (BOTTOM LEFT) BERNARD GREENBERG, (BOTTOM RIGHT) YLLA—RAPHO GUILLUMETTE

older alligators. Similarly young coachwhip snakes at first eat insects and, as they grow, eat small vertebrates.

Only the very largest of living snakes—the reticulated python (*Python reticulatus*), the Indian python (*P. molurus*), and the anaconda (*Eunectes murinus*)—are capable of eating large mammals such as small pigs and deer. Among crocodiles it is the largest species—the Nile crocodile (*Crocodylus niloticus*), the East Indian saltwater crocodile (*C. porosus*), and the Orinoco crocodile (*C. intermedius*)—that are known to attack and eat men. Presumably even larger prey was devoured by the great carnivorous dinosaurs such as *Allosaurus* and *Tyrannosaurus*, which were almost certainly capable of killing the largest of their herbivorous contemporaries.

Some carnivorous reptiles specialize on one or a few types of food. The gavial (*Gavialis gangeticus*) of India, a narrow-snouted crocodilian, feeds largely on fishes caught by quick sidewise sweeps of its head. The elongate, narrow snout encounters relatively little resistance in water, permitting the rapid movements necessary to catch such agile prey. By contrast the relatively broad snouts of other crocodilians prohibit the same kind of mobility because of the resistance they generate in water.

Other carnivorous reptiles have acquired the habit of eating mollusks. The cayman lizard (*Dracaena*) of northern South America, a snail feeder, has broad, flat-crowned rear teeth for cracking hard shells. This specialization was carried to an extreme by the extinct *Placodus*, which had teeth so broad that they reached halfway across the palate.

2. Dentition.—The dentition of most reptiles shows little specialization along the tooth row. A division into distinctive bladelike incisors, tusklike canines, and flat-crowned molars, such as characterize mammals, does not occur in reptiles. Instead the entire tooth row usually consists of long conical teeth, whether snakes, crocodilians, or dinosaurs are involved or whether the reptile eats reptiles, birds, or mammals. Venomous snakes have one or several hollow or grooved fangs, but these teeth have the same shape as most snake teeth. The principal differences between species lie in the number, length, and position of the teeth. Mammalian teeth are restricted to one row in the upper jaw and one in the lower. Crocodilians among the living forms and dinosaurs among the extinct forms have but a single upper and a single lower tooth row. Snakes and many extinct reptilian groups have teeth on the palatal bones (vomer, palatine, pterygoid) and on the bones of the upper jaw (premaxilla, maxilla); only one row of teeth is present on the lower jaw.

Lizards have conical or bladelike bicuspid or tricuspid teeth. Some species have conical teeth at the front of the jaws and cusped teeth toward the rear, but the latter are not comparable to the molars of mammals in either form (they are not flat-crowned) or function (they do not grind the food). Turtles, except for the earliest extinct species, lack teeth, and have instead two horny plates, an upper and a lower, that serve to bite off chunks of food.

The teeth of reptiles, less specialized in form than mammalian teeth, are also less specialized in function. A mammal with the typical mammalian tooth row can tear or bite off pieces of food (the incisors at the front), cut it up into smaller pieces (the premolars), and finally grind it up (the molars at the rear) before swallowing. The larger carnivorous reptiles (*e.g.*, crocodilians and certain dinosaurs) are equipped only to tear off or bite off large pieces of their prey and to bolt them without chewing. Insectivorous lizards (the majority of lizards) usually crack the exoskeleton of their insect prey, which are then swallowed without being ground up. Snakes simply swallow their prey whole without any mechanical reduction.

3. Skull and Joint Structures.—Many reptiles developed joints (in addition to the hinge for the lower jaw) within the skull, permitting at least slight movement of one part relative to others. The capacity for such movement within the skull is called kinesis and enables an animal to increase the gape of the mouth. It is thus an adaptation for swallowing large objects. Apparently some of the large carnivorous theropod dinosaurs (*e.g., Allosaurus*) had a joint between the frontal and parietal bones on the roof of the skull. All reptiles of the subclass Lepidosauria (lizards, snakes, rhynchocephalians, and the extinct eosuchians) have had kinetic skulls, but they differ from the dinosaurs in having the joint on the floor of the skull at the juncture of basisphenoid and pterygoid bones (fig. 5).

The skulls of the lepidosaurians became increasingly kinetic as new groups evolved. The Rhynchocephalia (which include the living tuatara) and their antecedents, the Eosuchia, had only the basisphenoidal-pterygoidal joint. The lizards lost the lower temporal bar, thereby freeing the quadrate bone and allowing greater movement to the lower jaw, which is hinged to the quadrate. Finally, in the snakes this trend culminates in the most kinetic skull among the vertebrates—a skull having the ancestral basisphenoidal-pterygoidal joint, a highly mobile quadrate (which gives even greater mobility to the lower jaw), upper jaws capable

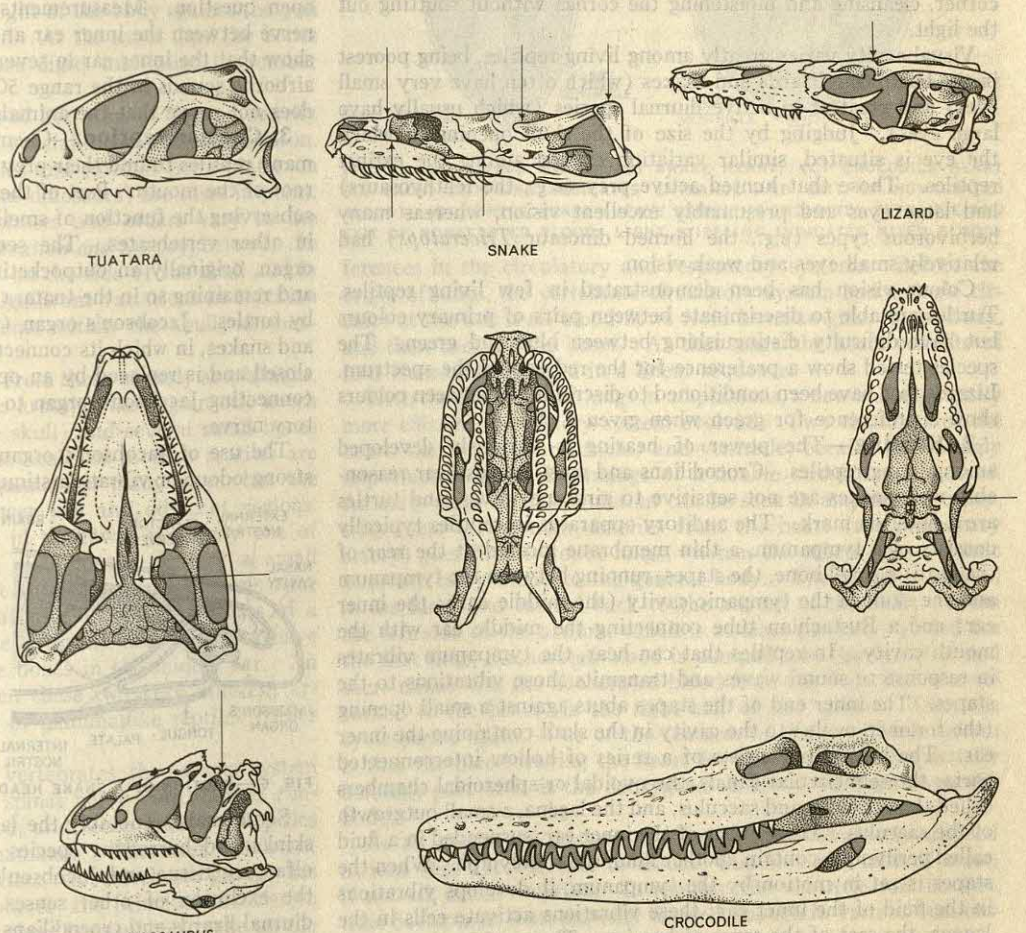


FIG. 5.—COMPARISON OF REPTILIAN SKULLS SHOWING POSITIONS (ARROWS) OF JOINTS OTHER THAN THOSE BETWEEN UPPER AND LOWER JAWS. THE TWO UPPER ROWS (LATERAL AND VENTRAL VIEWS) ARE OF LEPIDOSAURIAN REPTILES, THE BOTTOM ROW, OF ARCHOSAURS. THE CROCODILE SKULL HAS ONLY THE JOINT BETWEEN THE JAWS

of rotating on their longitudinal axes and of moving forward and backward, and often a hinge on the roof of the skull between the nasal and frontal bones that allows the snout to be raised slightly. In short, the only part of a snake's skull incapable of movement is the brain case.

B. Sense Organs

The sense organs of reptiles, as of most vertebrates, comprise organs for the detection and analysis of light, chemicals, and sound waves. Not all sense organs are equally developed in all reptiles; some species or groups of species rely heavily on sight, others on smell, and others on a combination. Some sense organs operate at a distance (*e.g.*, the eyes), others at very close range only (*e.g.*, taste buds).

1. Sight.—In general construction the eyes of reptiles are like those of other vertebrates. Accommodation for near vision in all living reptiles except snakes is accomplished by pressure being exerted on the lens by the surrounding muscular ring (ciliary body), which thus makes the lens more spherical. In snakes the same end is achieved by the lens being brought forward under pressure built up on the vitreous humour by contractions of muscles at the base of the iris. The pupil shape varies remarkably among living reptiles, from the round opening characteristic of all turtles and many diurnal lizards and snakes to the vertical slit of crocodilians and nocturnal snakes and the horizontal slits of a few tree snakes. Undoubtedly the most bizarre pupil shape is that of some geckos, in which the pupil contracts to form a series of pin holes, one above the other. The lower eyelid has the greater range of movement in most reptiles. In crocodilians the upper lid is more mobile. Snakes have no movable eyelids, their eyes being covered by a fixed transparent scale. The tuatara and all crocodilians have a third eyelid, the nictitating membrane, a transparent sheet that moves sideways across the eye from the inner corner, cleansing and moistening the cornea without shutting out the light.

Visual acuity varies greatly among living reptiles, being poorest in the burrowing lizards and snakes (which often have very small eyes) and greatest in active diurnal species (which usually have large eyes). Judging by the size of the skull opening in which the eye is situated, similar variation existed among the extinct reptiles. Those that hunted active prey (*e.g.*, the ichthyosaurs) had large eyes and presumably excellent vision, whereas many herbivorous types (*e.g.*, the horned dinosaur *Triceratops*) had relatively small eyes and weak vision.

Colour vision has been demonstrated in few living reptiles. Turtles are able to discriminate between pairs of primary colours but have difficulty distinguishing between blue and green. The species tested show a preference for the red end of the spectrum. Lizards that have been conditioned to discriminate between colours show a preference for green when given a choice.

2. Hearing.—The power of hearing is variously developed among living reptiles. Crocodilians and most lizards hear reasonably well, snakes are not sensitive to airborne waves, and turtles are a question mark. The auditory apparatus in reptiles typically consists of a tympanum, a thin membrane located at the rear of the head; a small bone, the stapes, running between the tympanum and the skull in the tympanic cavity (the middle ear); the inner ear; and a Eustachian tube connecting the middle ear with the mouth cavity. In reptiles that can hear, the tympanum vibrates in response to sound waves and transmits those vibrations to the stapes. The inner end of the stapes abuts against a small opening (the foramen ovale) to the cavity in the skull containing the inner ear. The inner ear consists of a series of hollow interconnected parts: the semicircular canals, the ovoidal or spheroidal chambers called the utriculus and sacculus, and the lagena, a small outgrowth of the sacculus. These tubes of the inner ear, suspended in a fluid called perilymph, contain another fluid, the endolymph. When the stapes is set in motion by the tympanum, it develops vibrations in the fluid of the inner ear; these vibrations activate cells in the lagena, the seat of the sense of hearing. The semicircular canals, as in all vertebrates, are concerned with equilibrium.

Most lizards can hear, though details of the acuity of hearing are largely unknown. The majority have a tympanum, tympanic cavity, and Eustachian tube. The tympanum, usually exposed at the surface of the head or at the end of a short open tube, may be covered by scales or may be absent. In general the last two conditions are characteristic of lizards that lead a more or less completely subterranean life and presumably do not hear airborne sounds. The middle ear of these burrowers is usually degenerate as well, often lacking the tympanic cavity and Eustachian tube.

Snakes have neither tympanum nor Eustachian tube, and the stapes is attached to the quadrate bone on which the lower jaw swings. It is unlikely that snakes can hear airborne sounds, although they are obviously sensitive to vibrations in the ground. A loud sound above a snake does not elicit any response provided the object making the sound does not move or provided its movements are not seen by the snake. On the other hand, the same snake will raise its head slightly and flick its tongue in and out rapidly if the ground behind it is tapped or scratched. Snakes undoubtedly "hear" these vibrations by means of bone conduction. Sound waves travel more rapidly and strongly in solids than in the air and are probably transmitted to the inner ear of snakes through the lower jaw, which is normally touching the ground, thence to the quadrate bone, and finally to the stapes. Burrowing lizards presumably hear ground vibrations in the same way.

Crocodilians, all of which have an external ear consisting of a short tube closed by a strong valvular flap and ending at the tympanum, have rather keen hearing. The American alligator (*Alligator mississipiensis*) can hear sounds within a range of 50–4,000 cycles per second. Hearing of crocodilians is involved not only in detection of prey and enemies but also in their social behaviour, for males roar or bellow either to threaten other males or to attract females.

Although turtles have well-developed middle ears and usually large tympanums, their ability to hear airborne sounds is still an open question. Measurements of the impulses of the auditory nerve between the inner ear and the auditory centre of the brain show that the inner ear in several species of turtles is sensitive to airborne sounds in the range 50–2,000 cycles per second, but this does not prove that the animals are aware of the sounds.

3. Chemoreception.—Chemical-sensitive organs, used by many reptiles to find their prey, are located in the nose and in the roof of the mouth. Part of the lining of the nose consists of cells subserving the function of smell and corresponding to similar cells in other vertebrates. The second chemoreceptor is Jacobson's organ, originally an outpocketing of the nasal sac in amphibians and remaining so in the tuatara and crocodilians. It has been lost by turtles. Jacobson's organ (fig. 6) is best developed in lizards and snakes, in which its connection with the nasal cavity has been closed and is replaced by an opening into the mouth. The nerve connecting Jacobson's organ to the brain is a branch of the olfactory nerve.

The use of Jacobson's organ is most obvious in snakes. If a strong odour or vibration stimulates a snake, its tongue is flicked in and out rapidly. Each time it is retracted the forked tip touches the opening of Jacobson's organ in the roof of the mouth, transmitting any chemical fragments adhering to the tongue. In effect, Jacobson's organ is a supplement to taste and is a short-range chemical receptor, as contrasted to the long-range testing of the true sense of smell located in the nasal tube.

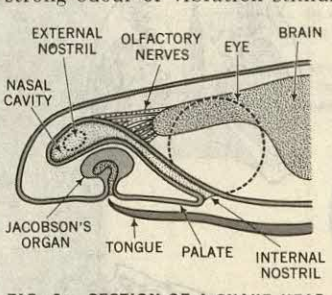

FIG. 6.—SECTION OF A SNAKE HEAD

Some snakes (notably the large vipers) and lizards (especially skinks and burrowing species of other families) rely upon the olfactory tissue and Jacobson's organ to locate food, almost to the exclusion of other senses. Other reptiles, such as certain diurnal lizards and crocodilians, appear not to use scent in searching for prey, though they may use their sense of smell for locating a mate.

Some snakes, notably pit vipers (rattlesnakes, etc.), boas, and

pythons, have special heat-sensitive organs on their heads as part of their food-detecting apparatus. Just below and behind the nostril of a pit viper is the pit that gives the group its common name. The lip scales of many pythons and boas have depressions (labial pits) that are analogous to the viper's pit. The labial pits of pythons and boas are lined with skin thinner than that covering the rest of the head and supplied with dense networks of blood capillaries and nerve fibres. The facial pit of the viper is relatively deeper than the boa's labial pits and consists of two chambers separated by a thin membrane bearing a rich supply of fine blood vessels and nerves. In experiments using warm and cold covered electric light bulbs, pit vipers and pitted boas have been able to detect temperature differences of less than 1° F (0.6° C).

Since many pit vipers, pythons, and boas are nocturnal and feed largely on mammals and birds, the facial sense organs enable them to direct their strikes accurately in the dark, once their warm-blooded prey arrives within range. The approach of the prey to that point is probably detected by the chemical receptors—either the nose, or Jacobson's organ, or both.

C. Internal Systems

1. Skeletal System.—The skeleton of reptiles fits the general pattern of that of all vertebrate animals. They have a bony skull, a long vertebral column that encloses the spinal nerve cord, ribs that form a bony basket around the viscera, and a framework of limbs.

Each group of reptiles developed its own particular variations on this major pattern in accord with the general adaptive trends of the group. Snakes, for example, have lost the limb bones, though a few retain vestiges of the hind limb. The limbs of several types of marine reptiles became modified into fins or flippers with obvious functional significance. In these groups, *e.g.*, the extinct ichthyosaurs and plesiosaurs, the bones of the limbs, no longer supporting the weight of the body against the pull of gravity, became much shortened. At the same time the bones that in other reptiles composed the digits multiplied in number forming a long flipper.

Groups of reptiles whose modes of life came to depend heavily on passive defense also developed specializations of the skeleton. The bony and horny shell of turtles and rows of bony plates on the back of ankylosaurs (Cretaceous dinosaurs) are cases in point.

The skulls of the several subclasses and orders vary in the ways mentioned below (see *Classification and Survey*, below). In addition to differences in openings on the side of the skull and in general shape and size, the most significant variations in reptilian skulls are those affecting movements within the skull, as mentioned above.

Reptilian skulls as a group differ from those of early amphibians, the vertebrates from which reptiles arose, in lacking an otic notch (an indentation at the rear of the skull) and several small bones at the rear of the skull roof. The skulls of modern reptiles are sharply set off from those of mammals in many ways, but the clearest differences are in the lower jaw and adjacent regions. Reptiles have a number of bones in the lower jaw, only one of which, the dentary, bears teeth. Behind the dentary a small bone, the articular, forms a joint with the quadrate bone near the rear of the skull. In mammals the lower jaw consists of a single bone, the dentary, and the articular and quadrate have become part of the chain of little bones in the middle ear. An almost complete transition between these two very different arrangements is known from fossils of mammallike reptiles (order Therapsida).

2. Nervous System.—As in all vertebrates, the nervous system of reptiles consists of a brain, a spinal nerve cord, nerves running from the brain or spinal cord, and sense organs. Reptiles have small brains compared to mammals. The most important difference between the brains of these two vertebrate groups lies in the size of the cerebral hemispheres, the principal associative centres of the brain. In mammals these hemispheres make up the bulk of the brain and, when viewed from above, almost hide the rest of the brain. In reptiles the relative and absolute size of the cerebral hemispheres is much smaller. The brain of snakes and alligators forms less than $\frac{1}{1,500}$ of the total body weight, whereas in mammals such as squirrels and cats, the brain accounts for about $\frac{1}{100}$ of the body weight. The differences are functionally related to the much feebler mental capacities of reptiles as compared to mammals.

The extent of variation in relative brain size in reptiles and its association with mode of life has not been studied intensively, but some notion of the variation can be obtained from the fact that a stegosaur (Stegosauria), roughly the size of an elephant, had a brain case no larger than that of an eight-foot crocodile, about large enough to contain a brain the size of a big walnut.

3. Circulatory System.—Modern reptiles do not have the capacity for rapid sustained activity found in birds and mammals. It is the general notion that this lower capacity is related to differences in the circulatory and respiratory systems. Before the origin of lungs, the vertebrate circulatory system had a single circuit: at the fish level blood flows from heart to gills, to the body, and then back to the heart. At that stage the heart consists of four chambers arranged in a linear sequence.

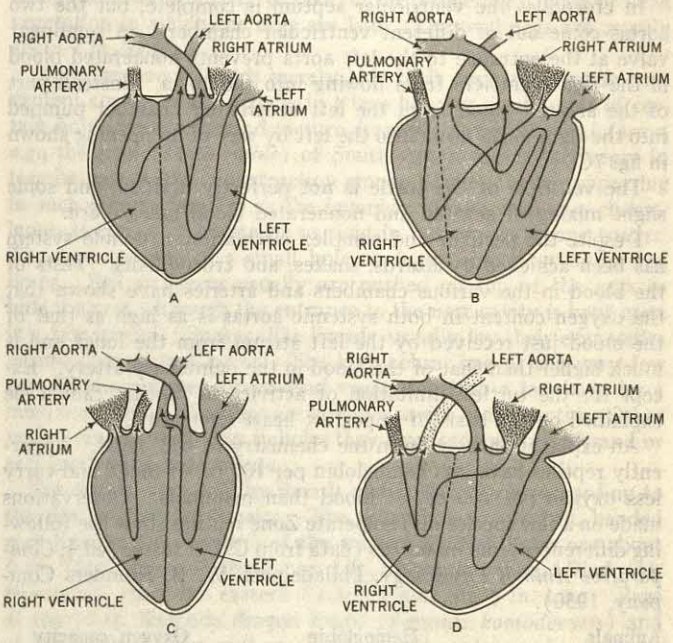

FIG. 7.—(A) LIZARD HEART; (B) SNAKE HEART; (C) CROCODILE HEART (IN EACH, STIPPLING INDICATES ENTRANCE AND EXIT OF NONAERATED BLOOD); (D) TURTLE HEART (HEAVY STIPPLING INDICATES ENTRANCE AND EXIT OF NONAERATED BLOOD; LIGHT STIPPLING INDICATES MIXED BLOOD)

With the evolution of lungs in amphibians, a new and apparently more efficient circulatory system evolved. Two chambers of the heart, the atrium (or auricle) and ventricle, became increasingly important, and the beginnings of a double circulation appeared. An early stage in this evolution can be seen in amphibians today, where one of the main arteries from the heart (the pulmonary artery) goes directly to the lungs, whereas the others (the systemic arteries) carry blood to the general body. The blood is aerated in the lungs and carried back to the atrium of the heart. From the left side of the atrium, which is at least partially divided for the first time, the aerated blood is pumped into the ventricle and there mixes with the nonaerated blood from the body that was returned to the heart via the right half of the atrium. Then the cycle begins again. One of the features of the amphibian system is that the blood leaving the heart for the body is only partially aerated; part of it is the deoxygenated blood returned from the body.

As all groups of modern reptiles have a completely divided atrium (fig. 7), it is safe to assume that this was true of most, if not all, extinct reptiles. In reptiles, the ventricle for the first time becomes at least partially divided, though in various fashions in the four major living groups.

When the two atria of a lizard's heart contract, the two streams of blood (aerated blood from the lungs in the left atrium and

nonaerated blood from the body in the right atrium) flow into the left chamber of the ventricle. As pressure builds up in that chamber, the nonaerated blood is forced through the gap in the partition into the right chamber of the ventricle. Then when the ventricle contracts, nonaerated blood is pumped into the pulmonary artery and thence to the lungs, while aerated blood is pumped into the systemic arteries (the aortas) and so to the body.

In snakes all three arterial trunks come out of one chamber of the ventricle, the one receiving the nonaerated blood of the right atrium. During ventricular contraction a muscular ridge forms a partition that guides the nonaerated blood into the pulmonary artery, while the aerated blood received by the other chamber of the ventricle is forced through the opening in the ventricular septum and out through the aortas.

In crocodiles the ventricular septum is complete, but the two aortas come out of different ventricular chambers. A semilunar valve at the entrance to the left aorta prevents nonaerated blood in the right ventricle from flowing into the aorta. Instead part of the aerated blood from the left ventricular chamber pumped into the right aorta flows into the left by way of an opening shown in fig. 7C.

The ventricle of the turtle is not perfectly divided, and some slight mixing of aerated and nonaerated blood takes place.

Despite the peculiar and complex circulation, a double system has been achieved by lizards, snakes, and crocodilians. Tests of the blood in the various chambers and arteries have shown that the oxygen content in both systemic aortas is as high as that of the blood just received by the left atrium from the lungs and is much higher than that of the blood in the pulmonary artery. Except for the turtles, limitation of activity in reptiles cannot be explained on the basis of imperfect heart circulation.

An explanation may lie in the chemistry of the blood. Apparently reptiles have less hemoglobin per 100 cc. of blood and carry less oxygen per 100 cc. of blood than mammals. Observations made on a few species of Temperate Zone reptiles show the following differences from mammals (data from C. L. Prosser [ed.], *Comparative Animal Physiology*, Philadelphia, W. B. Saunders Company, 1950).

Animals	Hemoglobin (per 100 cc. of blood)	Oxygen capacity (% by volume)
Reptiles	6–11 gm.	7–15
Mammals	11–17 gm.	16–29

4. Respiratory System.—The form of lungs and the methods of irrigating them may also influence activity by affecting the efficiency of respiration. In snakes the lungs are simple saclike structures having small pockets, or alveoli, in the walls. The lungs of many lizards and turtles and of all crocodilians have the surface area increased by the development of partitions that in turn have alveoli. As exchange of respiratory gases takes place across surfaces, an increase of the ratio of surface area to volume leads to an increase in respiratory efficiency. In this regard the lungs of snakes are not so effective as those of crocodilians. But the elaboration of the internal surface of lungs in reptiles is simple compared to that reached by mammalian lungs with their enormous number of very fine alveoli.

Most reptiles breathe by changing the volume of the body cavity. By contractions of the muscles moving the ribs, the volume of the body cavity is increased, creating a negative pressure, which is restored to atmospheric level by air rushing into the lungs. By contraction of body muscles, the volume of the body cavity is reduced, forcing air out of the lungs.

This system applies to all modern reptiles (and presumably the extinct ones as well) except turtles, which, because of the fusion of the ribs with the rigid shell, are unable to breathe by this means, though they use the same mechanical principle of changing pressure in the body cavity. Contraction of two flank muscles enlarges the body cavity, causing inspiration. Contraction of two other muscles, coincident with relaxation of the first two, forces the viscera upward against the lungs, causing exhalation.

The rate of respiration, like so many of the physiological activities of reptiles, is highly variable, depending in part upon the temperature and in part upon the emotional state of the animal.

5. Digestive System.—The digestive system of modern reptiles is similar in general plan to that of all higher vertebrates. It includes the mouth and its salivary glands, esophagus, stomach, and intestine, ending in a cloaca. Of the few specializations of the reptilian digestive system, the evolution of one pair of salivary glands into poison glands in the venomous snakes is outstanding.

6. Urogenital System.—During development the embryos of higher vertebrates (reptiles, birds, and mammals) use three separate sets of kidneys consecutively. They are arranged in longitudinal sequence in the body cavity. The first set, the pronephroi, are vestigial organs left over from the evolutionary past that soon degenerate and disappear without having had any function. The second set, the mesonephroi, are the functional kidneys of adult amphibians, but their only contribution to the lives of reptiles is in providing the duct (the Wolffian duct) that forms a connection between the testis and the cloaca. The operational kidneys of reptiles, birds, and mammals are the last set, the metanephroi, which have separate ducts to the cloaca. The principal function of the kidney is the removal of nitrogenous wastes resulting from the oxidation of proteins. Vertebrates eliminate three kinds of nitrogenous wastes: ammonia, urea, and uric acid. Ammonia and urea are highly soluble in water; uric acid is not. Ammonia is highly poisonous, urea slightly so, and uric acid not at all. Among reptiles the form taken by the nitrogenous wastes is closely related to the habits and habitat of the animal. Aquatic reptiles tend to excrete a large proportion of these wastes as ammonia in solution. This method, involving a great loss of body water, is no problem for an alligator, which eliminates between 40 and 75% of its nitrogenous wastes as ammonia. Terrestrial reptiles, such as most snakes and lizards, must conserve body water and convert their nitrogenous wastes to insoluble, harmless uric acid, which forms a more or less solid mass in the cloaca. In snakes and lizards these wastes are eliminated from the cloaca together with wastes from the digestive system.

Prior to the evolution of the metanephric kidney, the products of the male gonad, the testis, traveled through the same duct with the nitrogenous wastes from the kidney. But with the appearance of the metanephros, the two systems became separated. The female reproductive system never shared a common tube with the kidney. Oviducts in all female vertebrates arise as separate tubes with openings usually near, but not connected to, the ovaries. The oviducts, like the Wolffian ducts of the testes, open into the cloaca. Ovaries and testes lie in the body cavity near the kidneys.

With the evolution of the reptilian egg, internal fertilization became necessary. All modern reptiles, with the exception of the tuatara, have copulatory organs. Though these structures vary from group to group, they all include erectile tissue as an important element of the operating mechanism, and they all are protruded through the cloacal opening during copulation. Unlike the penis of turtles and crocodilians, the copulatory organ of lizards and snakes is paired, each unit being called a hemipenis. The hemipenes of lizards and snakes (fig. 8) are elongate tubular structures lying in the tail. Whereas the penis of a crocodile or turtle is protruded through the cloacal opening wholly by means of a filling of blood spaces (sinuses) in the penis, protrusion of a lizard's or snake's hemipenis is begun by a pair of propulsor muscles. Completion of the erection is brought about by blood filling the sinuses in the erectile tissue. Only one hemipenis is inserted into a female, but which one is a matter of chance. Unlike the penis of mammals, the copulatory organs of reptiles do not transport sperm through a tube. The ducts from the testes, as already mentioned, empty into

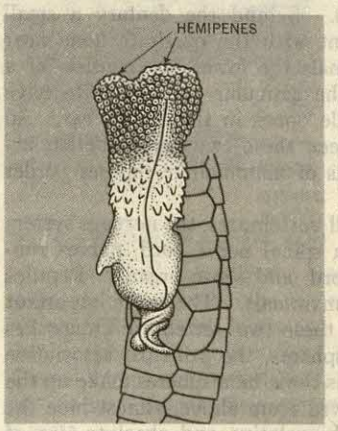

FIG. 8.—UNDERSIDE OF SNAKE BODY SHOWING ERECTED HEMIPENES

the cloaca, and the sperm flow along a groove on the surface of the everted penis or hemipenis.

IV. REPRODUCTION AND DEVELOPMENT

1. Courtship.—Courtship in some form is such a widespread prelude to mating among modern reptiles that it must have characterized many extinct groups as well. The male of some freshwater turtles, such as the red-eared turtle (*Pseudemys scripta elegans*) of the eastern United States, when courting orients himself in the water so that he is directly in front of the female and facing her. With his forefeet close together, the male vibrates his claws against her head (this display may vary with individuals). If the female is receptive, she swims forward slowly while the male backs away. Finally the female sinks slowly down. The male then mounts her from behind, clutching her shell with all four feet. His tail is brought under hers and his penis introduced into her cloaca.

The male of some terrestrial turtles, *e.g.*, the gopher tortoises (*Gopherus*) of North America, begins courtship by extending his neck and bobbing his head up and down. The courted female may bob her head in return. The male advances and nips at the female's shell, head, and neck and then circles her as she turns away from him. As soon as the female shows signs of response, the male mounts her shell from the rear and begins a series of pumping movements that bump the rear of his shell against the ground. Finally the female extends her tail, the male moves his tail into position, and copulation begins.

Males of the smaller box turtles (*Terrapene*) also nip at the female's shell, head, and neck, and, in addition, butt against her shell. After mounting the female and clasping her shell with his rear claws, the male leans backward off her shell in order to bring his tail under hers.

Male crocodilians bellow during the mating season, but it is not known whether this sound attracts receptive females or warns other males. The American alligator, which copulates in water, grasps the female's neck with his jaws and slips the end of his body under hers to enable him to insert his penis into her cloaca. Observations on courtship and copulation of other crocodilians are almost nonexistent.

Lizards have rather elaborate courtship patterns usually involving display and posturing by the males, who often have distinctive patches of colour on their throats or low on their sides. The male bobs up and down within sight of a female by bending and straightening his legs; the bobbing usually exposes the patches of colour, which may be blue, orange, red, or black depending on the species. Males of some species, such as the green anole (*Anolis carolinensis*) of southeastern United States, have throat dewlaps that are expanded during courtship, exposing brightly coloured skin. If the female seems receptive, the male approaches and straddles her back, often gripping her back or legs with his jaws. Just before copulation his tail is bent under hers.

The courtship patterns of snakes are simpler and usually consist of the male's crawling over the back of the female and often adopting every curve her body takes. In some types, for example the water snakes, the male rubs his chin against the female's back, whereas in other species, for example, the rattlesnakes (*Crotalus*), the male frequently nudges the female with his head. Male bull snakes (*Pituophis*) grasp the female's neck with their jaws during copulation.

When the male of a king cobra (*Ophiophagus hannah*) crawls on the back of a receptive female, he flicks his tongue against her repeatedly, with his head raised a few inches above her. During this procedure the female holds her head and neck off the ground and spreads her hood. The male nudges her neck and head with his snout and finally lifts the rear of her body with his tail. Up to this point the courting pair crawl slowly forward but cease to move when the male inserts his hemipenis into the female's cloaca. The duration of copulation in one pair of captive king cobras varied from 57 to 66 min. In other snakes it has been known to last more than two hours.

2. Methods of Reproduction.—The typical reptilian mode of reproduction is oviparous—the eggs are laid shortly after fertilization, and development of the embryos takes place largely after the eggs have been laid. This pattern characterizes crocodilians, turtles, the tuatara, most lizards and snakes, and many extinct reptiles. Fossil dinosaur eggs have been found in various parts of the world. The eggs may be deposited in a nest prepared by the female or simply laid under some convenient cover such as a rock or log.

Turtles and crocodilians invariably prepare a nest, and invariably it is the female that does the work. All turtles dig nests, scooping out a flask-shaped cavity in the ground with their hind feet. When the hole has reached the proper size, the spherical eggs, 1–1½ in. in diameter depending on the species, drop into the nest from the female's cloaca. The female scratches soil over the eggs, usually obliterating the nest site. Crocodilians either dig a nest along the bank of a river or lake, or heap together a mass of dead vegetation in which the eggs are laid. The oval eggs are usually about 2 in. long.

Most oviparous lizards merely hide their eggs under some convenient cover—under a rock, in a tree hole, or, in the case of certain house geckos, behind picture frames. A few tropical forms, *e.g.*, the tegu (*Tupinambis*) of South America, lay their eggs in termite nests. Nest construction among lizards, though appearing in such diverse families as the iguanids, skinks, and true chameleons, is not so elaborate or so rigid in pattern as among turtles. The nest consists of a small hole made by the snout or by the limbs. Soil or leaves usually are pushed on top of the eggs to hide the nest, although the entrance to the nest cavity is kept open in a few species. Snakes, like lizards, usually lay their eggs under natural, preexisting cover. The king cobra, one of the very few nest-building snakes, drags dead vegetation into a low heap by a bend in its body. The eggs are laid in a cavity at the centre. Other snakes deposit their eggs in holes they have scooped out of sand or soft earth with their snouts.

The size of eggs laid by lizards and snakes varies according to the size reached by females. The eggs of the 3- or 4-in. banded rock lizard (*Uta mearnsi*) of the western United States are about ⅝ in. long, those of the 1- to 2-ft. ringneck snake (*Diadophis punctatus*) from the eastern United States are ½ in. long. Eggs of the 10-ft. Komodo dragon lizard (*Varanus komodoensis*) and of the 20-ft. Indian python (*Python molurus*) are about 4½ in. long.

A minority of modern and extinct reptiles are (and were) livebearing, or viviparous. Strictly speaking, most of this minority are not truly viviparous, but ovoviviparous, because the embryos develop with their shells or shell membranes intact and are nourished wholly by the yolk. In a few modern reptiles the embryonic membranes and the tissues lining the oviducts of the females come into close contact and are modified in one of several ways to provide a temporary organ though which food and respiratory gases are exchanged. In the simplest reptilian "placenta," the most superficial layer (the epithelium) of the outer embryonic membrane and of the lining of the oviduct partially degenerates, thereby bringing the blood vessels of embryo and mother closer together. The approximation of the two bloodstreams facilitates the exchange of oxygen and carbon dioxide, this gas exchange being the only function of the organ at this stage of evolution. Several Australian snakes (*Denisonia superba* and *D. suta*) and a number of lizards—the common East Indian brown-sided skink (*Mabuya multifasciata*), the cylindrical skink (*Chalcides ocellatus*) of southern Europe and North Africa, and the Australian blue-tongued skink (*Tiliqua scincoides*), as examples—are known to have this type of organ, and presumably many ovoviviparous reptiles do.

The best-developed reptilian "placentas" consist of apposed, thickened, folded elliptical areas of the outer embryonic membrane and lining of the oviduct. The ridges of the oviductal areas are filled with blood vessels, and the epithelium between ridges is thickened and glandular. Usually eggs developing with this type of "placenta" have less yolk; food and oxygen are transmitted from mother to embryo. Several species of Australian lizards and the common European viper (*Vipera berus*) are known to provide this type of internal environment for their developing young.

The line between oviparity (egg laying) and ovoviviparity

(hatching eggs in the mother's body) is arbitrary. Females of some lizards and snakes retain the fertilized eggs in their bodies for a few days before laying them. Other species retain the eggs for most of the developmental period, hatching occurring shortly after laying. For the grass snake of England (*Natrix natrix*) the lapse of time between copulation and egg laying is usually two months; the young hatch six to ten weeks later. The interval between mating and egg laying is one month in the Texas horned lizard (*Phrynosoma cornutum*). Ovoviviparous species may be closely related to oviparous ones. For example, the horned lizards (*Phrynosoma*) of southwestern United States and Mexico are usually oviparous, but the species *P. douglassi* is ovoviviparous. The bunchgrass lizard (*Sceloporus scalaris*), an inhabitant of mountains in Arizona, is ovoviviparous, whereas most of its lowland relatives, such as the eastern fence lizard (*S. undulatus*), lay eggs.

As a final complication in this pattern, a given species may be ovoviviparous in parts of its range and oviparous elsewhere. A European lizard, *Lacerta vivipara,* living within the Arctic Circle, presumably would be unable to reproduce in the short cool summer if it laid eggs. The female by moving about the environment and remaining in the sunlight for long periods can maintain a sufficiently high body temperature to permit successful development of the embryos held within her body. In central Europe this lizard lives rather high in the mountains and retains its ovoviviparous habits in the cool climate. Farther south in the Pyrenees, where the sunlight is stronger and the summer longer, *L. vivipara* is oviparous.

Not all instances of ovoviviparity in reptiles are related to life in cooler climates. The water snakes of the southern United States and those of southern China live in similar climates, yet the American species are ovoviviparous and the Chinese species oviparous. The sea snake family, Hydrophidae, includes a group of ovoviviparous genera that never come ashore. A remarkable fossil discovery has confirmed that the extinct marine ichthyosaurs were also live-bearers. As reptilian eggs cannot develop successfully in water, a thoroughly marine reptile must either suffer through the awkwardness of coming ashore to lay its eggs, as do marine turtles, or become ovoviviparous. Live-bearing in the sea snakes and ichthyosaurs represents part of their general adaptation to a completely marine life.

3. Number of Offspring.—The number of eggs in a clutch or offspring in a brood varies from one to 200 among living reptiles; presumably similar variation occurred among the extinct types. Crocodilians lay from 20 to 70 eggs, turtles from one to 200. In turtles, more so than in crocodiles, the number varies with the species and roughly with the size attained by females of the particular species. The big marine turtles have the largest clutches (usually more than 100), the smaller land and freshwater turtles, much smaller ones. The number of eggs or young is not so closely related to the size of mature females in species of lizards and snakes. With few exceptions, lizards of the family Gekkonidae lay two eggs at a time regardless of the size of the female. Lizards of the family Scincidae have broods varying from 2 to about 30. One of the largest members of this latter family, the foot-long stump-tailed skink (*Tiliqua rugosa*) of Australia, has only two young at a time, whereas the Great Plains skink (*Eumeces obsoletus*) of the United States usually lays between 10 and 20 eggs in a clutch.

Clutch size in the five-foot bull snake (*Pituophis catenifer*) and coachwhip snake (*Masticophis flagellum*) of western United States is usually 10 or 12; in the two- to three-foot grass snake of England and Europe it is 30–40; in the giant reticulated python of Southeast Asia and the East Indies it may reach 100.

4. Parental Care.—Parental care of eggs and newborn young is not well developed or elaborated among reptiles. Female crocodilians generally remain in the vicinity of their nests and chase would-be predators from the site. In a few lizards, for example, the Great Plains skink, the female returns to the nest between feeding excursions to coil around the eggs and turn them at intervals. The male and female king cobra remain in the vicinity of the nest, and one of the parents usually is coiled above the egg cavity. Females of at least several species of pythons form nests of sorts by coiling around their eggs and thereby pulling them into a heap. They leave the eggs only to drink. Turtles and the great majority of egg-laying lizards and snakes abandon their eggs once they are laid.

5. Incubation Period.—The incubation (or gestation) period of reptilian eggs is affected by many factors to such an extent that it is difficult to assign a figure characteristic of a given species. One source of complication is the combining of oviparous and ovoviviparous habits by certain species. The eggs of the Great Plains skink or of the European grass snake may develop within the female's body for a month or more and then continue to develop for two months after laying. The fact that the female retains the eggs for varying lengths of time makes measurement of the incubation period uncertain and of doubtful significance. The eggs of wholly ovoviviparous species may be considered as incubating under special circumstances. To simplify this discussion the developmental period of the embryo, whether developing within the female's body or outside it, will be referred to as the gestation period.

In general, the gestation period lasts 60–105 days in most American and European reptiles. The eggs of the American alligator hatch about 63 days after laying, those of the small eastern fence lizards (*Sceloporus undulatus*) in about the same time. The gestation period in the common European viper lasts 60–90 days. Eggs of marine turtles hatch 30–75 days after they are laid, depending on the site.

The temperatures to which a brood is subjected will shorten or lengthen gestation according to whether the temperatures are high or low. During the course of long-range observation, the gestation period of the common garter snake (*Thamnophis sirtalis*) of the United States has varied from 87 days during the warmest year to 116 days during the coolest. Rattlesnakes in southern California have gestation periods varying from 140–295 days, depending on the species and the prevailing temperatures.

6. Growth.—Once hatched, reptiles normally grow at a much more rapid rate than is commonly supposed. Prevalent notions about the growth of reptiles are based on captive animals, which only rarely are provided the kind of environment and diet that will enable them to achieve their inherent growth rate. Giant Galapagos tortoises kept under nearly ideal conditions have been known to increase their weight from 7–13 lb. up to 179–183 lb. in nine years; shell length doubled in that period. Smaller species also grow rapidly, although the absolute magnitude of the change is of course much smaller. The box turtle of the United States has a shell about 1½ in. long at the end of its first year; at the end of five years its length has doubled; growth is slower after that.

Under good conditions a one-year-old American alligator is about 2 ft. long and weighs about 4 lb. At the end of six years males average about 6 ft. and about 80 lb. In the following three years length will increase approximately 1½–2 ft. and weight about 50 lb. The red diamond rattlesnake is about 12 in. long at birth, grows to about 26 in. in its first year, reaches about 34 in. by the end of its second year, and grows more slowly after that. The much smaller common garter snake is roughly 6¾ in. at birth, 14½ in. at the end of its first year, 19 in. at the end of its third, and thereafter grows at a much diminished rate. The pattern for lizards is much the same: rapid growth early in life and slow growth afterward. The significant difference between growth in reptiles and that in mammals is that an individual reptile has the potential of growing throughout its life, whereas an individual mammal reaches a terminal size and does not grow any more, even though it subsequently lives many years in ideal conditions.

Because reptiles may continue to grow throughout their lives, the maximum size of any species is difficult to determine. As might be guessed, the maximum size of the largest snake or largest crocodile is considerably less than estimated by excitable and gullible travelers. Persistent but wholly unsubstantiated reports are heard of 40-ft. anacondas. This gigantic South American snake, granting it may be the largest living species, probably never exceeds 30 ft. The reticulated python of Southeast Asia and the East Indies has been recorded at 28 ft. and 250 lb. The rock python (*Python sebae*) of Africa reaches 25 ft. No other group of living snakes comes close to the pythons and boas in weight,

although the king cobra of Asia and the East Indies comes close in length (18 ft.) and is much the longest venomous snake. The heaviest venomous snake is probably the eastern diamondback rattlesnake (*Crotalus adamanteus*), which though not exceeding 8 ft. may weigh as much as 34 lb. The largest of the common non-venomous snakes of the family Colubridae is probably the Oriental rat snake, *Zaocys carinatus* (12 ft. 3 in.).

Four living species of crocodilians grow larger than 20 ft.: the American crocodile (*Crocodylus acutus*), the Orinoco crocodile (*C. intermedius*), the saltwater crocodile (*C. porosus*), and the gavial (*Gavialis gangeticus*). The last two may approach 30 ft.

The giant among living turtles is the marine leatherback (*Dermochelys*), which reaches a total length of about nine feet and a weight of about 1,500 lb. The largest of the land turtles is a Galapagos tortoise weighing 560 lb.

The largest modern lizard is a monitor, the Komodo dragon of the East Indies, growing to a length of ten feet. Two or three other species of monitors reach six feet. The common iguana comes close to that size, but no other lizard does.

None of the living reptiles, with the possible exception of snakes, is as large as the largest extinct representative of its particular group. The 9-ft. leatherback turtle was exceeded by a 12-ft. marine turtle (*Archelon*). No modern crocodile approaches the estimated 50-ft. *Phobosuchus*. The Komodo dragon does not compare with the 20-ft. or more mosasaur *Tylosaurus*. These extinct giant relatives of living reptiles had two things in common: they lived during the Cretaceous and they were marine. None of these, however, compares with the herbivorous sauropod dinosaurs such as *Brontosaurus* (*Apatosaurus*), *Diplodocus*, and *Brachiosaurus*, the largest of which was about 80 ft. long and probably weighed close to 50 tons.

The length of time needed to reach sexual maturity varies greatly among reptiles and, though roughly related to the size usually attained by the species, is even more closely related to the climate in which the animal lives. The red diamond rattlesnakes in southern California, for example, bear their first young when three years old, whereas the northern Pacific rattlesnake (*Crotalus viridis oreganus*) bears its first litter when four years old. The much smaller common garter snake is sexually mature shortly before it is two years old.

The 5- to 6-in. long northwestern sagebrush lizard (*Sceloporus graciosus gracilis*), living in the Sierra Nevada range of California at an elevation (about 6,000 ft.) where it has, at most, six months of activity each year, requires two years or more to reach sexual maturity. Another lizard, the green anole (*Anolis carolinensis*), similar in size to the sagebrush lizard but living in the lowlands of southern United States, may reach maturity in four or five months in Florida.

Turtles mature at a slower rate. Females of the red-eared turtle of the central United States lay their first eggs when they are from three to eight years old, depending upon how long it takes them to reach a shell length of 6 in. Females of the musk turtle or stinkpot (*Sternotherus odoratus*) in Michigan require 9 to 11 years to mature, at which time their shells are 3 to 4 in. long. Presumably turtles living in the tropics and having much longer growing seasons mature more rapidly.

7. Longevity.—The maximum age, meaning the potential longevity, of modern reptiles varies greatly and can be determined only from records of captive animals. Turtles as a group seem capable of living longer than the others, and 31 species have been kept in captivity more than 20 years. Several species are said to have lived 150 years or more, but these may be cases of two individuals whose periods of captivity overlapped. It is almost a certainty, though yet to be proven, that some turtles can live more than 50 years. There is no reliable evidence for believing that the giant land tortoises live much longer than some smaller species. The crocodilians that have been kept in captivity the longest are two alligators (an *Alligator mississipiensis* and an *A. sinensis*), both of which have survived in zoos for slightly more than 50 years. Several species of pythons and boas have lived longer than 20 years, the maximum being 28 years for the anaconda. A black-lipped cobra (*Naja melanoleuca*) has been kept 29 years. Lizards seem to have an upper limit near that of snakes, though fewer species have been kept over 20 years. The record for lizards is held by a slowworm, *Anguis fragilis* (32 years), followed by the European glass snake, *Ophisaurus apodus* (25 years).

The life expectancy for most reptiles in nature remains a mystery, but it certainly is much lower than the maxima achieved in captivity and probably is related to the length of time needed to reach sexual maturity.

V. DISTRIBUTION

A. Fossil Reptiles

The geographic distribution of extinct reptiles is not and cannot be perfectly known because of lack of fossilization in some areas and destruction of fossils in others by natural geological forces. But what is known of the fossil record shows that most of the major groups, or orders, were worldwide or nearly so at some time in their individual histories. Few orders are known from South America and Australia; the absence of most major groups from these areas more likely is explained on the basis of lack of preservation or lack of discovery of fossil beds than on the basis of a genuine absence of the animals throughout such a long interval as the Mesozoic. In the following discussion the names of present-day continents are used, though it should be understood that continental outlines in the past did not always coincide with today's.

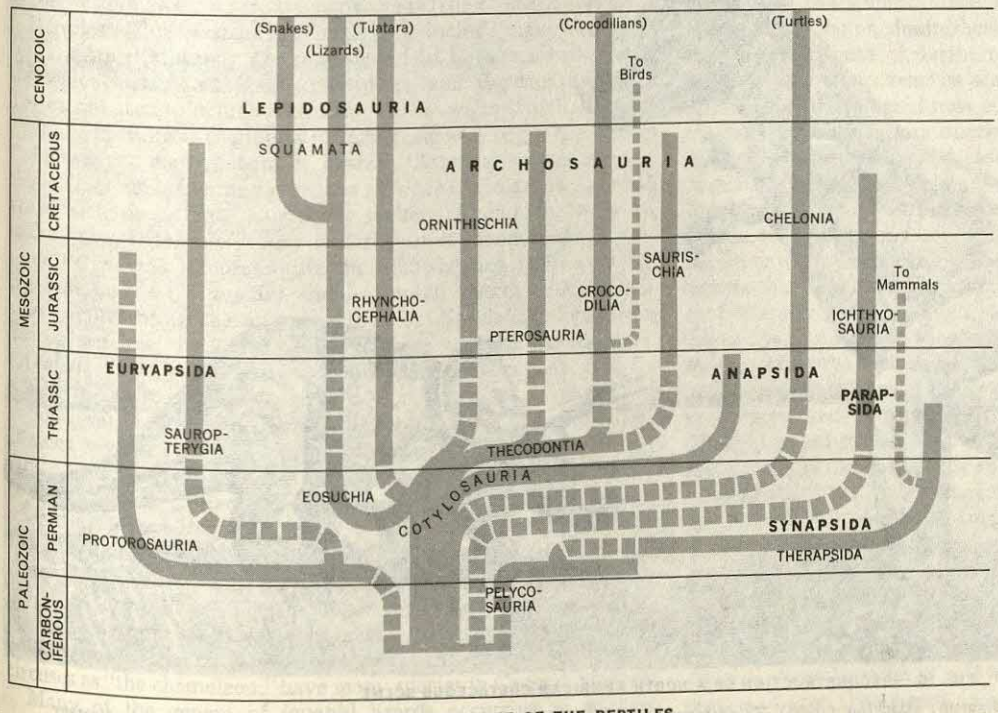

FIG. 9.—FAMILY TREE OF THE REPTILES

Few orders of reptiles are known from Pre-Mesozoic times (*i.e.*, Carboniferous and Permian). The stem reptiles, the Cotylosauria, have been found in Carboniferous deposits of eastern and western North America and western Europe and in Permian beds of Russia and Africa. Presumably they also lived in Asia during this interval of over 100,-

000,000 years, but their remains have yet to be found there. In the same period the Pelycosauria lived in North America and Europe, where their fossils are well known, and possibly in Africa and Asia. At least the related mammallike Therapsida were fossilized in Africa and Europe. The probable ancestors of turtles appeared in Africa and the first diapsids (reptiles having two-arched temporal structures) in Africa and Europe in the Permian.

By the Triassic, the earliest portion of the Mesozoic, the mammallike reptiles had spread to all of the continents except Australia. Turtles (Chelonia) were still in Africa and had spread at least to Europe. The Ichthyosauria were living in seas covering what is now western North America and western Europe and may have been much more widely distributed, considering their oceanic habitat. North America at that time was also the home of primitive diapsids (Thecodontia), of phytosaurs (suborder Phytosauria), and the earliest dinosaurs (Saurischia) and crocodiles (Crocodilia). Besides the mammallike therapsids, Eurasia and Africa in the Triassic had phytosaurs, the first Rhynchocephalia, and the early dinosaurs. The major groups of reptiles, therefore, were essentially worldwide in distribution by the Triassic.

The giant dinosaurs began their efflorescence in the Jurassic. The big carnivorous types, such as *Allosaurus*, roamed the landscapes of the major continents, presumably preying on even larger herbivorous dinosaurs (*Brontosaurus, Diplodocus,* etc.), whose remains have been found in North America, Europe, Africa, and Australia. Marine ichthyosaurs and plesiosaurs (order Sauropterygia) still swam in the shallow seas of both hemispheres. The ornithischian dinosaurs (Ornithischia), the ancestors of the duck-billed and horned dinosaurs, became widely distributed in the Jurassic. One group, the armoured stegosaurians (suborder Stegosauria), left fossils in North America, Europe, and Africa. The flying reptiles (Pterosauria) also made their appearance at least in Africa and Europe during the Jurassic.

The culmination of dinosaur evolution occurred in the Cretaceous, when every part of the world had its herbivorous ornithischian dinosaurs: the ankylosaurs (suborder Ankylosauria), medium-sized dinosaurs armoured with heavy plates and large spines, that ranged ffom South America to Africa; the duck-billed dinosaurs (suborder Ornithopoda) ranging from North America to Africa; and the horned dinosaurs (suborder Ceratopsia) from North America and Asia. Everywhere they were preyed upon by the big carnivorous types, which culminated in North America in the gigantic carnivore *Tyrannosaurus*. The skies over North America, Africa, and Europe (and probably Asia and South America as well) were the province of the flying reptiles (Pterosauria). Meanwhile there were inconspicuous groups that later inherited the reptilian world. Lizards (suborder Sauria) appeared in most continents and snakes (suborder Serpentes) in some places. Birds, having splintered off from reptilian ancestors in the Jurassic, became more numerous in the Cretaceous; mammals, which ultimately replaced most of the reptiles, were represented on most continents by small creatures.

Through all this evolutionary activity, the conservative turtles continued their plodding evolutionary pace, changing but little, yet lasting through it all. *See* also PALEONTOLOGY.

B. LIVING REPTILES

Though living reptiles are primarily tropical animals, many inhabit the Temperate zones. The northernmost ranges are those of the lacertid lizard (*Lacerta vivipara*) and the common viper (*Vipera berus*), both of Europe and Asia. These ovoviviparous species live north of the Arctic Circle, at least in Scandinavia. Two other lizards, the slowworm (*Anguis fragilis*) and the sand lizard (*Lacerta agilis*), and two snakes, the grass snake (*Natrix natrix*) and the smooth snake (*Coronella austriaca*), reach 60° N in Europe. Of these six northern species, all but the grass snake are

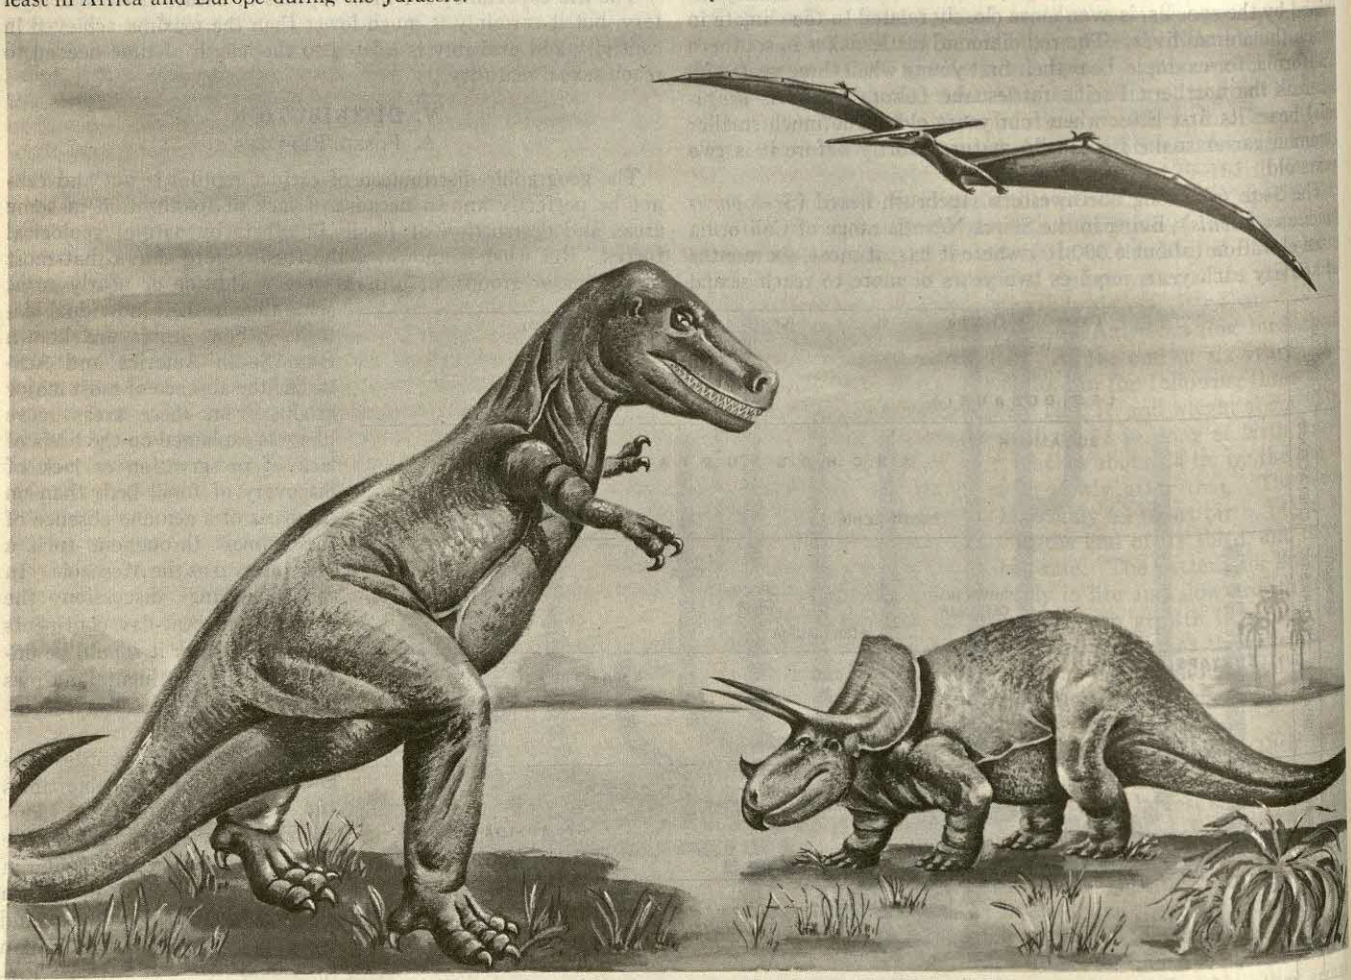

FIG. 10.—RECONSTRUCTION OF A NORTH AMERICAN CRETACEOUS SCENE

(Left) *Gorgosaurus*, a theropod dinosaur, attacking (right) *Triceratops*, an ornithischian dinosaur. (Above) *Pteranodon*, an advanced pterosaur

ovoviviparous. Across Siberia only *Lacerta vivipara* and the *Vipera berus* live north of 60°. The difference in northward distributions in Europe and Asia reflects the amelioration of the climate in western Europe effected by the warm Gulf Stream.

In North America no reptile reaches the 60th parallel. Two species of garter snakes live as far north as 55° in western Canada, and one of these species, the common garter snake (*Thamnophis sirtalis*), is the only reptile reaching 50° N in eastern Canada. As all garter snakes are ovoviviparous, seven of the eight northernmost reptiles of both land masses have this development pattern. In North America, the northern limit of turtles and lizards is about 55° N in western Canada. In Eurasia the northernmost turtle is found at 55° N.

It is only south of 40° N that reptiles become abundant. In eastern United States and eastern Asia water snakes (*Natrix*), rat snakes (*Elaphe*), racers (*Coluber*), green snakes (*Opheodrys*), northern skinks (*Eumeces*), glass "snakes" (lizards of the genus *Ophisaurus*), and soft-shelled turtles (*Trionyx*) are common elements of the faunas. One of the two living species of *Alligator* lives in southeastern United States; the other lives in China. Though both regions are characterized by many species of emydid turtles (family Emydidae), the genera to which these species belong usually are found in only one region or the other. For example, the common emydid turtles of the eastern United States are the painted turtles (*Chrysemys*), cooters and sliders (*Pseudemys*), box turtles, and map turtles (*Graptemys*). None of these genera is found in Eurasia. Lizards, aside from the northern skinks and the so-called glass snakes, of the various areas differ. Many lizards of temperate Eurasia belong to the families Agamidae and Lacertidae, which do not occur at all in the Americas. On the other hand, many lizards of North America are in the families Iguanidae and Teiidae, which do not live in Eurasia.

Oddly enough, the fauna of eastern United States is almost as distinct from that of western United States and northern Mexico (which is faunistically part of the same region) as it is from that of eastern Asia. Eastern United States has many genera and species of emydid turtles; western United States (defined by a diagonal line running southeast and northwest through Texas, then northward along the continental divide) has only four or five species. Few genera and species of iguanid lizards inhabit the eastern United States, whereas the western United States has many. Although the eastern United States has more species of water snakes, the western United States contains more garter snakes. More species of snakes appear in the eastern United States than in the western areas, where the converse is true of lizard species.

Reptiles of the North Temperate Zone include many ecological types. Aquatic groups are represented in both hemispheres by the water snakes, many emydid turtles, and the two alligators. Terrestrial groups include tortoises (*Terrapene* in North America, *Testudo* in Eurasia), ground dwelling snakes (*e.g.*, the racers, *Coluber*), and many genera of lizards. Arboreal snakes are few, the main group being the rat snakes (*Elaphe*), and arboreal lizards are almost nonexistent. Burrowing snakes are common, the worm snake (*Carphophis amoenus*) and the short-tailed snake (*Stilosoma extenuatum*) representing the blunt-headed burrowers and the bull snakes (*Pituophis*) and leaf-nosed snakes (*Phyllorhynchus*) representing the auger burrowers. Specialized burrowing lizards are few; in North America there are the legless lizard (*Anniella*), two worm lizards (family Amphisbaenidae), and the sand skink (*Neoseps*).

Southward in Central America the reptile fauna becomes richer. Besides several turtle families (snapping turtles [Chelydridae], mud and musk turtles [Kinosternidae], sliders [Emydidae], etc.) found in eastern United States, Central America has three genera of turtles (*Dermatemys, Claudius,* and *Staurotypus*) not living elsewhere. Crocodilians become more numerous in terms of species and individuals; there are no alligators, but caymans and true crocodiles occur here. The significant increase in the fauna results from the increase in lizards and snakes. The anoles, represented over most of southern United States by the one species sold at circuses as "the chameleon," have many species in Central America.

Many of the genera of iguanid lizards occurring in western United States have species in Mexico; one genus of spiny lizards (*Sceloporus*) reaches its peak of numbers of species in Mexico. South of Mexico the North American iguanid genera disappear and are replaced by tropical groups such as the black iguanas (*Ctenosaura*), the helmeted iguanids (*Corythophanes*), the casque-headed iguanids (*Laemanctus*), and the basilisks (*Basiliscus*). The lizard family Teiidae, though represented in the United States by the race-runner genus (*Cnemidophorus*), is tropical, and its real development begins in Central America with the large, conspicuous, and active ameivas (*Ameiva*) and several small secretive genera.

Among snakes, the fer-de-lance genus *Bothrops,* the coral snakes (*Micrurus*), the rear-fanged snakes such as the cat-eyed snakes (*Leptodeira*), and nonvenomous genera such as the tropical green snakes (*Thalerophis*) either appear for the first time or begin their proliferation of species in Central America.

These groups become increasingly numerous in northern South America, the heartland of the American tropics. Vine snakes (*Oxybelis* and *Imantodes*), false coral snakes (*Erythrolamprus*), slender ground snakes (*Drymobius*), and the burrowing spindle snakes (*Atractus*) have their headquarters there. Almost all of the genera of the lizard family Teiidae occur in this area. The iguanid lizards of the anole genus (*Anolis*) seem almost to have exploded in northern South America, as most of the approximately 165 species live there. Other iguanid genera, *e.g.*, the long-legged iguanids, *Polychrus,* make their appearance.

Crocodilians are still more numerous in terms of species than in Central America. In addition to the common American crocodile (*Crocodylus acutus*) and the common spectacled cayman (*Caiman sclerops*), which occur in Central America, tropical South America has the big Orinoco crocodile (*Crocodylus intermedius*), the black cayman (*Melanosuchus niger*), the smooth-fronted caymans (*Paleosuchus*), and several species of spectacled caymans (*Caiman*).

Turtles are also abundant in South America. Some of the North American groups, for example the mud turtles (*Kinosternon*) and sliders (*Pseudemys*), are represented, but the majority of species are members of genera and even families (*e.g.*, the side-necked turtles, families Pelomedusidae and Chelidae) unknown in temperate North America.

Several groups that form important, if not dominant, elements of the fauna of the Eastern Hemisphere are largely or completely absent from the American tropics: the lizard families Scincidae, Lacertidae, Chamaeleontidae, and Agamidae, and the snakes of the cobra (*Naja*) and water snake (*Natrix*) genera.

South of the tropics in the Temperate Zone of South America, the reptilian fauna diminishes rapidly. Crocodilians and turtles do not occur south of northern Argentina. One snake, an ovoviviparous pit viper, reaches almost 50° S in Argentina, and two iguanid lizards range almost to 55° S.

Apart from the genera of reptiles listed above as common to the eastern United States and eastern Asia, the Temperate Zone of Eurasia is noted for its many lizards of the families Agamidae, Lacertidae, and to lesser degrees Gekkonidae and Scincidae. These lizards are mostly terrestrial; a few are burrowers; but almost none are aquatic or arboreal. The extremely specialized burrowers among them are desert-dwelling skinks (*Ophiomorus* and *Scincus*) that literally swim through sand with the help of countersunk lower jaws and sharp snouts. Most of the snakes characteristic of this vast area are also terrestrial; the racers, common vipers, and Asian ground snakes (*Contia*) are examples. Arboreal snakes are represented almost exclusively by the rat snakes (*Elaphe*). The leaf-nosed snakes (*Lytorhynchus*) and the sand boas (*Eryx*) are the distinctive burrowing snakes of the region. Except for the Chinese alligators, temperate Eurasia lacks crocodilians. Over this vast area a few species of turtles are found, and they are about equally divided between land tortoises (*Testudo*) and freshwater genera (*Emys, Clemmys,* and *Trionyx*).

A few types characteristic of the Oriental tropics lap over into the margins of the Temperate Zone, *e.g.*, several rear-fanged snakes (*Boiga trigonata* and *Psammodynastes*), a cobra or two (*Naja*), several species of soft-shelled turtles (*Trionyx*), and some species of true chameleons (*Chamaeleo*).

In the Oriental tropics, embracing India, Ceylon, southeastern Asia, the Philippines, and most of the East Indies, the reptilian fauna is extremely rich in species and diverse types. Aquatic groups are represented by snakes of various genera (*e.g., Natrix, Enhydris, Cerberus,* etc.), several groups of lizards (*Tropidophorus* among the skinks and *Hydrosaurus* among the agamids), many emydid and soft-shelled turtles, and five species of crocodiles. The numerous terrestrial reptiles include the small kukri snakes (*Oligodon*), the big Oriental rat snakes (*Ptyas* and *Zaocys*), cobras, monitor lizards (*Varanus*), many species and genera of skinks, some geckos, and several land turtles (*Cuora, Testudo*). Specialized, blunt-headed burrowing snakes (*e.g., Calamaria*) and lizards (*e.g.,* the family Dibamidae and the skink genus *Brachymeles*) are also abundant.

But the distinctive life forms of reptiles in this great region of humid forest are arboreal. Heavy-bodied pythons and Oriental pit vipers (*Trimeresurus*); slender, green, long-headed vine snakes (*Dryophis*); slender, blunt-headed, slug-eating snakes (*Pareas*); and the widespread, thick-bodied rat snakes give some idea of the variation among arboreal snakes. Lizards of bush and tree habitats may be long legged and green (as *Calotes cristatellus*), or brown and black (*Gonyocephalus*), or short legged and gray and brown (many geckos). Some climb only with the aid of claws (*e.g.,* the monitors), a few with the help of prehensile tails (*e.g.,* the deaf agamids, *Cophotis*), and many with the help of clinging pads under the digits (*e.g.,* many geckos). The most striking arboreal reptiles of this area are the flying lizards (*Draco*) and the parachuting gecko (*Ptychozoon*), which has fully webbed digits, a fringed tail, and wide flaps of skin along its sides.

Though geographically part of the East Indies, New Guinea has a reptilian fauna more akin to that of Australia, and these two areas will be considered as one. The Australian region is the only area in the world in which venomous species of snakes outnumber the harmless species. The family Colubridae, comprising the great majority of the nonvenomous or slightly venomous snakes of the world, is poorly represented in Australia, which has only 12 species. New Guinea, being more tropical and closer to the true Oriental tropics, has 22, which is less than the number (33) living in the much smaller Temperate Zone state of Kansas. The place of the colubrids in the Australian region is taken by snakes of the cobra family. The fauna also includes a few pythons and minute blind snakes (family Typhlopidae); a variety of geckos, skinks, and agamid lizards; side-necked turtles; and three species of crocodiles.

The reptilian fauna of Africa forms two main divisions. The first of these, the fauna of the North African coast, is akin to that of central and southwestern Asia and southern Europe and is therefore partly a Temperate Zone fauna. The racers, the burrowing sand skink (*Scincus*), and the emydid turtle *Clemmys leprosa* are elements of temperate fauna in North Africa. Some species of the great tropical fauna lying south of the Sahara occur in North Africa and in Southwest Asia. Examples are the sand snakes (*Psammophis*), cobras, and the chameleons (family Chamaeleontidae). As is true of the temperate fauna of Eurasia, the North African reptiles, though representing many families, are principally terrestrial and burrowing. Many lacertid and agamid lizards scamper over rocks and sand by day to be replaced at night by small geckos. They are preyed upon by the racers (*Coluber*) and sand snakes (*Psammophis*). In addition to cobras, the venomous snakes of North Africa include the common vipers, the saw-scaled viper (*Echis carinatus*), and the horned vipers (*Cerastes*). The last two are true desert animals, the horned vipers using sidewinding locomotion like that of the sidewinder rattlesnake of the American deserts. Land tortoises (*Testudo*) are common in this semiarid land. Until the 1860s, the Nile crocodile came far down the river but has now been exterminated in southern Egypt.

The second and much larger division of the African fauna is the great tropical assemblage that ranges down to the Cape of Good Hope. In common with tropical Asia, this vast area has cobras, many skinks, and many geckos. Its fauna differs from that of Asia in the absence of pit vipers (subfamily Crotalinae), the near-absence of emydid turtles, and in the poor representation of agamid lizards. But these groups are replaced in tropical Africa by the many true vipers (subfamily Viperinae), the side-necked turtles (family Pelomedusidae), and the lacertid lizards. Chameleons and land tortoises have their centres of development here. Four species of crocodiles, including the two dwarf crocodiles (*Osteolaemus*), occur in Africa.

In Africa are found all of the diverse reptilian types characteristic of a tropical area: aquatic turtles, crocodiles, and snakes (including *Boulengerina,* a member of the cobra family); terrestrial turtles, snakes and lizards; burrowing snakes of the blunt-headed and auger types; limbless and virtually blind burrowing lizards; and a profusion of arboreal snakes and lizards.

The large island of Madagascar off the eastern coast of Africa has a peculiar fauna that appears in part as a collection of castoffs, groups that in Africa have not been able to meet the competition of more advanced forms. For example, there are no agamid lizards; instead their place is taken by iguanid lizards whose ancestors were undoubtedly exterminated in Africa long ago. Madagascar and its small neighbouring islets are the home of the Sanziniinae, an odd group of snakes of the family Boidae. With few exceptions the reptiles of Madagascar belong to genera found there only. The exceptions are the chameleons (genus *Chamaeleo*) found also in Africa, a side-necked turtle (*Podocnemis*) also living in South America, the land tortoises of the genus *Testudo,* so common in Africa, and several geckos that, as a group, seem better able to cross water barriers than most reptiles. *See* also ANIMALS, DISTRIBUTION OF; ZOOGEOGRAPHY.

VI. CLASSIFICATION AND SURVEY

A. CLASSIFICATION

Although the vast majority of reptiles have become extinct, living species number close to 6,000. The living and fossil forms are classified below, with living orders extended to families to show their general diversity.

The following classification may differ from arrangements given in related articles elsewhere in the encyclopaedia, particularly in regard to orders and families. These differences reflect the opinions of the various authors concerned.

Class Reptilia (reptiles)
- Subclass Anapsida ("stem reptiles" and turtles)
  - Order Cotylosauria ("stem reptiles," extinct)
  - " Chelonia (turtles and tortoises)
    - Family Chelydridae (snapping turtles)
    - " Kinosternidae (musk and mud turtles)
    - " Dermatemydidae (Central American river turtles)
    - " Platysternidae (big-headed turtles)
    - " Emydidae (freshwater turtles)
    - " Testudinidae (tortoises)
    - " Cheloniidae (sea turtles)
    - " Pelomedusidae (side-necked turtles)
    - " Chelidae (snake-necked turtles)
    - " Carettochelidae (pitted-shelled turtles)
    - " Trionychidae (soft-shelled turtles)
    - " Dermochelyidae (leatherback turtles)
- Subclass Synapsida (forms leading to mammals, extinct)
  - Order Pelycosauria (primitive mammallike reptiles, extinct)
  - " Therapsida (advanced mammallike reptiles, extinct)
- Subclass Parapsida (marine reptiles, extinct)
  - Order Mesosauria (small aquatic reptiles, extinct)
  - " Ichthyosauria (fishlike reptiles, extinct)
- Subclass Euryapsida (extinct reptiles)
  - Order Protorosauria (various obscure reptiles, extinct)
  - " Sauropterygia (marine reptiles, plesiosaurs and their relatives, extinct)
    - Suborder Nothosauria (primitive, chiefly marine reptiles, extinct)
    - " Plesiosauria (turtlelike marine reptiles, extinct)
    - " Placodontia (armoured turtlelike reptiles, extinct)
- Subclass Lepidosauria (diapsid reptiles)
  - Order Eosuchia (ancestral diapsids, extinct)
  - " Rhynchocephalia (tuatara and fossil relatives)
  - " Squamata (lizards and snakes)
    - Suborder Sauria (lizards)
      - Family Gekkonidae (geckos)
      - " Iguanidae (iguanids)
      - " Agamidae (agamids)
      - " Chamaeleontidae (chameleons)
      - " Xantusiidae (night lizards)
      - " Scincidae (skinks)
      - " Dibamidae (skink relatives)
      - " Anelytropsidae (skink relatives)

Family Gerrhosauridae (gerrhosaurids)
" Lacertidae (lacertids)
" Teiidae (teiid lizards)
" Amphisbaenidae (worm lizards)
" Varanidae (monitors)
" Pygopodidae (snake lizards)
" Helodermatidae (Gila monsters)
" Anguidae (glass snakes and alligator lizards)
" Xenosauridae (xenosaurids)
" Shinisauridae (Chinese crocodile lizards)
" Anniellidae (footless lizards)
" Cordylidae (girdle-tailed lizards)
Suborder Serpentes (snakes)
Family Typhlopidae (blind burrowing snakes)
" Leptotyphlopidae (blind burrowing snakes)
" Uropeltidae (burrowing snakes)
" Aniliidae (burrowing snakes)
" Xenopeltidae (burrowing snakes)
" Boidae (boas and pythons)
" Colubridae (colubrid snakes)
" Elapidae (cobras, coral snakes, and relatives)
" Hydrophidae (sea snakes)
" Viperidae (vipers)
Subclass Archosauria ("ruling reptiles")
Order Thecodontia (ancestors of crocodiles and dinosaurs, extinct)
Suborder Phytosauria (phytosaurs; crocodilelike reptiles, extinct)
Order Crocodilia (crocodiles, alligators, and gavials)
Family Alligatoridae (alligators and caymans)
" Crocodylidae (crocodiles)
" Gavialidae (gavials)
Order Saurischia (reptilelike dinosaurs, extinct)
Suborder Theropoda (bipedal carnivorous dinosaurs, extinct)
" Sauropoda (quadrupedal, primarily herbivorous dinosaurs, extinct)
Order Ornithischia (birdlike dinosaurs, extinct)
Suborder Ornithopoda (duck-billed dinosaurs, extinct)
" Stegosauria (plated dinosaurs, extinct)
" Ankylosauria (armoured dinosaurs, extinct)
" Ceratopsia (horned dinosaurs, extinct)
Order Pterosauria (flying reptiles, extinct)

B. Survey

The major divisions, called subclasses, of the class Reptilia are defined by the number and position of openings in the skull behind the eye socket, or orbit, as shown in fig. 11.

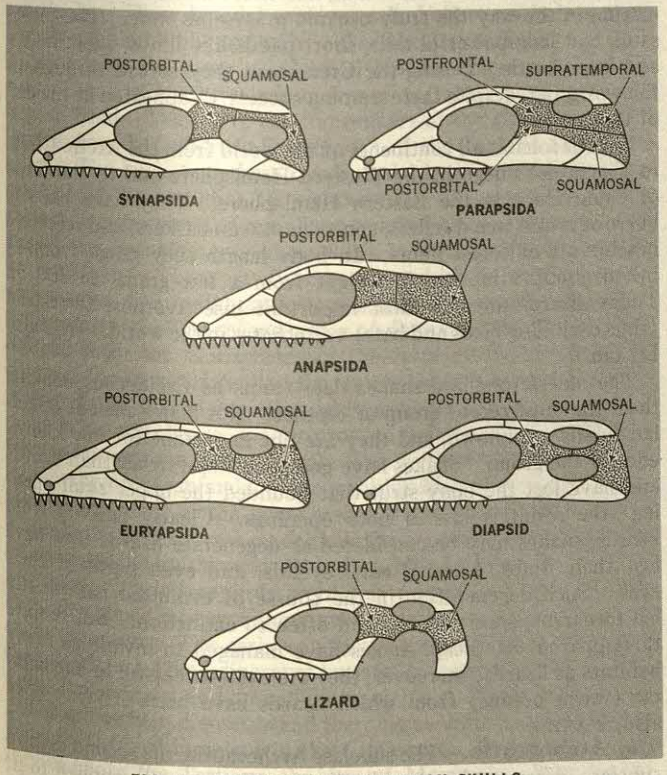

FIG. 11.—DIAGRAMMATIC REPTILIAN SKULLS
Skull differences illustrate the basis for major subdivisions of reptiles. The lizard has a modified diapsid skull

1. Anapsida.—The earliest reptiles, belonging to the subclass Anapsida, had closed skulls without any openings behind the orbit. This subclass includes two orders, the stem reptiles and the turtles.

Cotylosauria.—The order Cotylosauria, the primitive stem reptiles from which all of the other reptilian groups were derived,

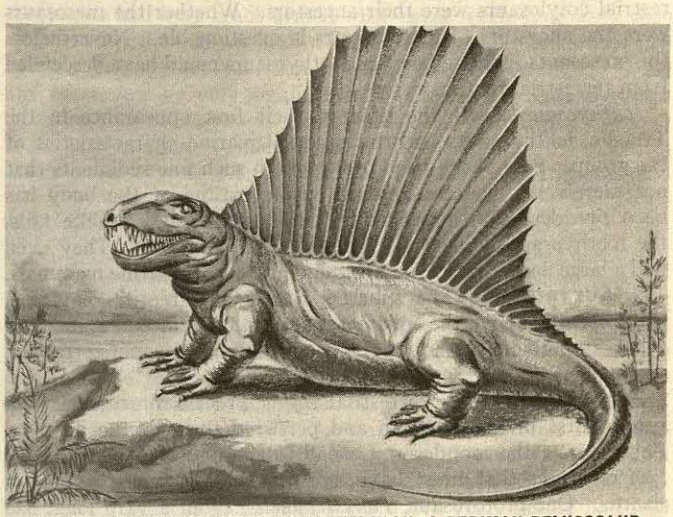

FIG. 12.—RECONSTRUCTION OF DIMETRODON, A PERMIAN PELYCOSAUR

arose from amphibians in the Carboniferous and survived into the Triassic. Most of the known cotylosaurs were small or moderate (about six feet long) in size, low-slung, and stocky. Most were carnivorous but a few, judging by the teeth, were herbivorous.

Chelonia.—The turtles, order Chelonia, appeared fully developed in the Triassic and apparently arose from a small Permian reptile, *Eunotosaurus*, from Africa. With the exception of *Eunotosaurus*, all members of this order have a complete shell (formed of bone and, usually, horny scutes) that completely encloses the shoulder and pelvic girdles. From their earliest history onward they have included terrestrial and aquatic types.

Terrestrial turtles tend to have high-domed shells and stumpy feet regardless of the group to which they belong. The giant Galapagos tortoises (*Testudo*), the box turtles of North America (*Terrapene*), and the Malayan box turtle (*Cuora amboinensis*) all fit this general pattern. Aquatic turtles tend to have flatter profiles and webbed toes, a pattern found in such diverse families as the pond turtles (Emydidae), soft-shelled turtles (Trionychidae), and side-necked turtles (Pelomedusidae). The side-necked turtles represent one of the principal divisions of the order Chelonia. Most contemporary turtles pull their heads straight back into their shells by bending the neck into a vertical curve; these are the so-called cryptodire ("hidden neck") turtles. The side-necked, or pleurodire, turtles merely turn their necks to one side and press the head tightly against the fore leg or shoulder. (*See* also TURTLE.)

2. Synapsida.—The subclass Synapsida, reptiles having a single opening in the skull below the squamosal and postorbital bones, are called mammallike reptiles because of their later history. They comprise two orders.

Pelycosauria.—The order Pelycosauria ran through its life span in the late Carboniferous and Early Permian as elongated reptiles. Some pelycosaurs developed very long bony projections from the vertebrae that probably supported a membranous "sail" extending two or three feet above the back in a six-foot animal.

Therapsida.—The second group of synapsids, the order Therapsida, arose in the Permian and, after diverging into carnivorous and herbivorous forms, gradually acquired mammalian characteristics of dentition and limb orientation during the Triassic. Although they did not survive beyond that time, in the Jurassic period that followed they were replaced by several groups of mammals, all evidently derived from the Therapsida.

3. Parapsida.—The subclass Parapsida, reptiles having a single skull opening behind the eye and above the supratemporal and postfrontal bones, comprises the order Ichthyosauria and, tentatively, the order Mesosauria.

Mesosauria.—Found in deposits of the Late Carboniferous, the mesosaurs were small aquatic reptiles (about two feet long) having a deep flattened tail, short paddlelike limbs, and a long slender snout typical of fish-eating reptiles. Despite this aquatic specialization, the skeleton of mesosaurs clearly shows that the terrestrial cotylosaurs were their ancestors. Whether the mesosaurs were the ancestors of ichthyosaurs is questionable. Nevertheless the mesosaurs indicate how the ichthyosaurs could have descended from terrestrial reptiles.

Ichthyosauria.—At the time of their first appearance in the Triassic, ichthyosaurs had the essential marine characteristics of the group. Some have been preserved in such fine sediments that not merely the skeleton but the whole outline of the body has been revealed. With their short finlike limbs and fishlike tails, the ichthyosaurs looked like long-snouted porpoises. They even had a large fleshy dorsal fin, like many of today's marine mammals.

4. Euryapsida.—The subclass Euryapsida, reptiles having a skull opening above the squamosal and postorbital bones, includes other amphibious or aquatic groups, as well as some terrestrial forms.

Protorosauria.—The terrestrial forms, order Protorosauria, appeared first in the Permian and persisted through the Triassic. Some were rather nondescript, small (about one foot long), lizardlike creatures that must have lived much like many of today's lizards. One protorosaur, *Tanystropheus,* about a yard long, had a slender neck making up almost half of its total length, a short body, and normal-proportioned limbs and tail (compared to the body). The habits of this strange creature can only be guessed at.

Sauropterygia.—The protorosaurs gave rise to the order Sauropterygia, which was composed of three suborders: the aquatic Nothosauria, Plesiosauria, and Placodontia. All had the upper elements of the shoulder and pelvic girdle reduced and the ventral elements expanded—a typical aquatic modification showing deemphasis of supporting the body weight. The limbs of nothosaurs and placodonts, both of which appeared in the Triassic, could probably have been used for walking, but not the paddlelike limbs of the plesiosaurs. The placodonts had broad flat teeth in massive jaws, suggesting that they cracked mollusk shells. The plesiosaurs, found first in Jurassic deposits, were the most specialized of the subclass and probably never came ashore. Comments on their means of locomotion and probable means of getting food appear elsewhere in this article.

5. Lepidosauria.—The subclass Lepidosauria is one of two subclasses of reptiles that have what is called a diapsid skull, that is, one having two openings behind the eye, one above the squamosal and postorbital bones and one below them. It appeared first in the Late Permian and was represented then by the order Eosuchia.

Eosuchia.—The earliest diapsid was a small creature, lizardlike in general proportions and probably in habits. Several Triassic and Cretaceous reptiles, including one similar in form to crocodiles, are placed in the same order.

Rhynchocephalia.—A second group of lepidosaurians, order Rhynchocephalia, arose in the Triassic and survives today as the tuatara (*Sphenodon*) of New Zealand. The rhynchocephalians or beak-heads, so-called because of a small overhang of the upper jaw, did not go much beyond the basic pattern of the earliest eosuchians. Their dentition was specialized compared to that of the more primitive eosuchians, their teeth being fused to the jaws instead of set in sockets. Never very important in the world's fauna, the rhynchocephalians died out in the Cretaceous, leaving only the tuatara in its isolated range.

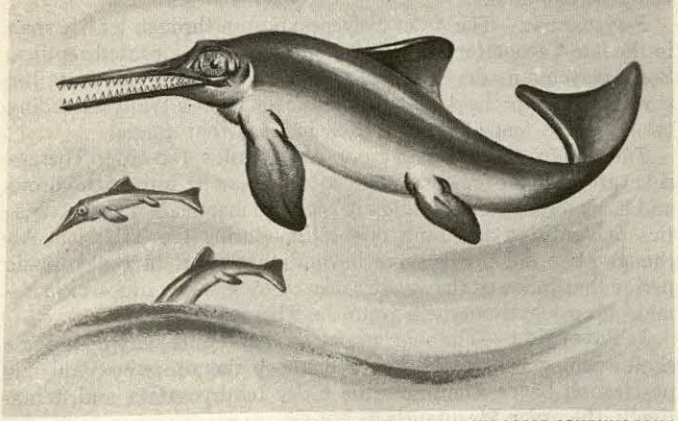

FIG. 13.—RECONSTRUCTION OF STENOPTERYGIUS, A JURASSIC ICHTHYOSAUR

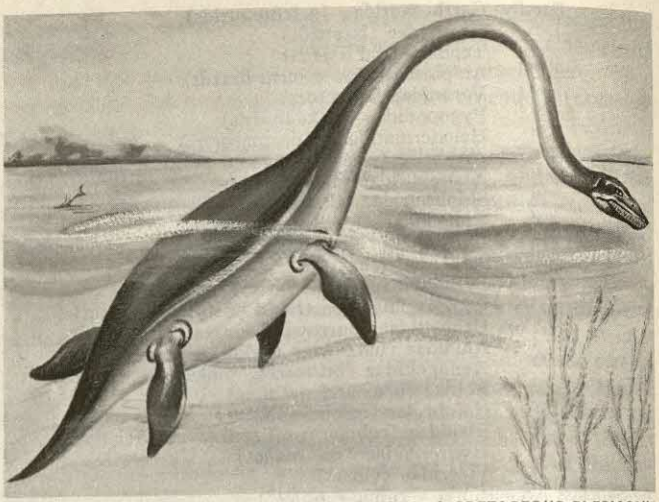

FIG. 14.—RECONSTRUCTION OF ELASMOSAURUS, A CRETACEOUS PLESIOSAUR

Squamata.—The last of the lepidosaurians to appear, the order Squamata, comprising lizards and snakes, were the only truly successful ones in the sense that they became widespread, numerous, and important components of the natural community. Lizards, first found in Jurassic deposits, have lost the bony strut that ran underneath the lower opening in the diapsid skull. Presumably the lizards are descended from a primitive eosuchian. Except for one group, the mosasaurs (Mosasauridae), fossil lizards show no specializations not found in contemporary forms. Only one modern lizard, the Galapagos marine iguana (*Amblyrhynchus cristatus*), lives in the sea. But this shore-limited iguanid is not marine in the way the truly oceanic mosasaurs were. The mosasaurs had long powerful tails, short paddlelike limbs, short necks, and large heads. During the Cretaceous they spread throughout the world but, despite their seeming success, disappeared at the end of that period.

Lizards inhabit all continents of the world from the Arctic Circle to Tierra del Fuego in the Western Hemisphere and to the Cape of Good Hope in the Eastern Hemisphere. They have become burrowers and tree dwellers, conspicuous sun baskers, and secretive inhabitants of forest floors. In body length they range from 1½ in. to about 5 ft., and in weight from a few grams to 300 lb. Today lizards are the most important insectivorous, terrestrial (thus excluding birds and bats) vertebrates in the world. (*See* also LIZARD.)

The oldest fossilized snakes date from the Cretaceous, making them the most recent group of reptiles. Not many ancient ophidian fossils are known, and they are not important for our knowledge of the group. Snakes have gone one step farther than lizards and have lost the bony strut that bounded the upper skull opening; the result is loss of both openings. Clearly derived from lizards, snakes may be considered as degenerate lizards that have lost their limbs, external ears, eyelids, and even parts of their eyes. Such degeneration in the course of evolution has usually led to narrow specialization and often to extinction. But despite this apparent handicap, snakes have managed to invade as many habitats as lizards; moreover, they are even successful in one habitat (warm oceans) from which lizards have been driven. (*See* also SNAKE.)

6. Archosauria.—The subclass Archosauria, the second diapsid subclass, deserves the name "ruling reptiles" usually applied to it, for they dominated the land fauna of the Mesozoic, an era lasting about 140,000,000 years. All had teeth set in sockets, which dis-

tinguishes them from all the diapsid lepidosaurians except the eosuchians.

Thecodontia.—Starting in the Early Triassic as the order Thecodontia, the first archosaurs were small (about one to three feet long) carnivorous reptiles without conspicuous specializations except for bipedal tendencies. In fact these generalized thecodonts had all the characteristics that should have been shown by the ancestors of the remaining groups of ruling reptiles. Though the thecodonts did not live beyond the Triassic, it would be a mistake to say that they became extinct then; rather, they evolved into the other ruling reptiles.

Crocodilia.—The order Crocodilia, one of the Triassic descendants of the thecodonts, differs very little from the theocodonts in its skeleton, which is all that is known of these early reptiles. Only the palate of the first crocodilians shows the basic aquatic specialization that they maintained virtually unchanged down to the present. The bones of the upper jaw and palate meet along the midline, forming a solid roof to the mouth and the floor of a pair of bony tubes running from the external nostrils to the rear of the mouth. The internal nostrils open behind a fleshy valve in the mouth and thus permit a crocodile to breathe while only the tip of its snout is above the surface.

Modern crocodilians have been placed in three families (or subfamilies—opinions differ): Alligatoridae, including alligators and caymans; Crocodylidae, the true crocodiles; and Gavialidae, the gavials. The last family is distinguished by an extremely long slender snout and by the separation of certain bones (nasals and premaxillaries) of the skull that meet in the other two groups. The teeth of the lower jaw fit inside those of the upper jaw in the alligators and caymans, whereas in true crocodiles the teeth of the two jaws form an interdigitating row when the jaws close. (*See* also CROCODILIA.)

Saurischia.—The order Saurischia, one of two orders of dinosaurs, also appeared in the Triassic. The more primitive dinosaurs of this order were bipedal and carnivorous and are grouped in the suborder Theropoda. They were relatively small (about 3 ft. long), and their skulls were similar to those of the thecodonts. Still in the Triassic, larger and heavier carnivorous types appeared, culminating in the Jurassic and Cretaceous in the huge bipedal *Allosaurus* (about 34 ft.) and *Tyrannosaurus* (about 47 ft.), respectively. These bipedal carnivores had short weak fore limbs and strong hind limbs and tails. (*See* also DINOSAUR.)

Along with the more usual small bipedal dinosaurs, there appeared some with relatively long front legs, rather blunt teeth, and a small head. They were the forerunners of the gigantic amphibious sauropods (suborder Sauropoda) of the Jurassic and Cretaceous. The longest of these quadrupedal herbivores, *Diplodocus*, reached 87 ft., including its slender tail. *Brontosaurus*, though shorter, was heavier and may have weighed close to 30 tons. The largest was *Brachiosaurus*, about 80 ft. long and probably weighing nearly 50 tons. These massive creatures evidently lived in marshes and swamps, their weight at least partially supported by the water.

Ornithischia.—The second order of dinosaurs, the Ornithischia, differed from the saurischians in the form of the pelvic girdle. Whereas the saurischians had the simple pubic bone and triradiate pelvis of the thecodonts, the ornithischians had a two-pronged pubic bone and, hence, a four-pronged pelvis. The saurischians were carnivorous at first and only later in their history developed into herbivorous animals. The ornithischian dinosaurs, lacking teeth at the front of the jaws, probably had horny beaks instead. These herbivorous forms made their first appearance in the Jurassic as bipedal Ornithopoda (the duck-billed dinosaurs and their relatives). Their fore limbs were only moderately shortened and never developed into grasping organs, as in the case of some saurischian dinosaurs. The early ornithopodans gave rise not only to the varied duck-billed dinosaurs but also to quadrupedal armoured (*e.g.*, *Stegosaurus*) and horned dinosaurs (*e.g.*, *Triceratops*).

The saurischian dinosaurs had their big evolutionary burst in the Jurassic, the ornithischians in the Cretaceous. But neither group survived into the Tertiary, the Age of Mammals. None of the varied explanations for their disappearance—change in climate, epidemics, reduction of swamps through mountain formation, egg eating by early mammals, etc.—seems adequate, and even all the explanations taken together cannot account for the total extinction of this fantastic group of animals.

Pterosauria.—The last group of archosaurs, order Pterosauria, the flying reptiles, appeared in Early Jurassic times. The first pterosaurs had long heads armed with sharp teeth, long tails, and well-developed wings, as known from some remarkably preserved fossils. Later pterosaurs had much reduced tails, larger wings, and often few or very small teeth. Like most archosaurs, the flying reptiles did not survive the Cretaceous Period.

REPTON, HUMPHRY (1752–1818), a leading English architect and landscape gardener of his time, was born in Bury St. Edmunds, Suffolk, on April 21, 1752. A financial setback soon after his marriage in 1773 caused him to retire from his mercantile business in Norwich but not until 1788 did he decide to exploit his gift for drawing and interest in landscape gardening. Lancelot ("Capability") Brown's death five years before had left no comparable genius, and Repton quickly established a wide reputation for himself as a designer. His gift for drawing led him to prepare schemes for his clients in the form of books, usually bound in red leather, containing his written proposals, illustrated by watercolour sketches, many of which had movable flaps to show the "before" and "after" effects. He claimed to have prepared about 400 of these Red Books, though less than half that number appear to have survived. Repton's landscapes were seldom as large in extent as Brown's, and tended to be more thickly planted. He advocated a gradual transition between house and grounds by means of terraces, balustrades, and steps, and took a particular interest in details such as cottages, lodges, conservatories, and "winter corridors." He was influenced by the Picturesque movement, which admired wild landscapes, though he was drawn into conflict with its leading protagonists, Richard Payne Knight and Uvedale Price, the former having attacked him in a footnote to his poem *The Landscape* (1794). He was conscious of the relation of architecture to landscape, and he collaborated for some years with John Nash. (*See* LANDSCAPE ARCHITECTURE.) He died at Hare Street, Romford, Essex, on March 24, 1818.

In addition to several essays and a short play, Repton published three major books on landscape gardening, *Sketches and Hints on Landscape Gardening* (1795), *Observations on the Theory and Practice of Landscape Gardening* (1803), and *Fragments on the Theory and Practice of Landscape Gardening* (1816).

See biographical notice in *The Landscape Gardening and Landscape Architecture of the late Humphry Repton*, ed. by J. C. Loudon (1840); Dorothy Stroud, *Humphry Repton* (1962). (D. ST.)

REPTON, a township in Derbyshire, Eng., about 8 mi. (13 km.) SW of Derby by road. Pop. (1961) 1,850. Its famous boys' school was founded in 1557 by Sir John Port; the modern buildings incorporate considerable portions (restored) of an Augustinian priory established in 1172. There was a monastery in the 7th century, the first bishop of Mercia being established there. The parish church of St. Wystan has pre-Conquest work in the chancel, and beneath is a remarkable Saxon crypt, part of the wall of which may have been included in the original monastery chapel.

REPUBLIC, a term denoting (1) a state not ruled by a monarch or emperor; (2) a state where power is not directly in the hands of or subject to complete control by the people, in contrast with a democracy (*q.v.*); (3) more loosely, any regime where government depends actually or nominally on popular will. The latter meaning is implied more generally in the adjective, "republican," than it is in the noun.

"Republic" derives from the Latin words *res publica*, "public affair" or "thing." That concept was in turn loosely equivalent to the classical Greek *ta koinonia*, "common things" or "property," a term

originally applied in the early city-state to the city's treasure, the public funds, and then by analogy coming to symbolize and denote the common interests. From these root origins derive in turn the concepts of commonwealth, which was the official title of Great Britain under Oliver Cromwell's rule, the first republic in the English-speaking world, and common weal or common welfare, at that same time a widely held designation of the proper end or purpose of government.

The term republic has generally been applied by historians first to the government of ancient Rome after the expulsion of the Etruscan kings, the Tarquins, and prior to the establishment of the empire by Augustus. During that period, indeed, political institutions, constitutional arrangements and the locus of effective political power varied widely, though the regime might be generally described as one of aristocratic, or patrician, ascendancy moderated by popular, or plebeian, influence and assent. But the dual concepts which subsequently characterized the republican idea, absence of monarchy and a collective public interest and business, were present.

Some historians have also applied the term to the ancient Greek city-state. There, however, governments were normally classified by the numbers exercising power, such as monarchy, aristocracy and democracy, and their perversions, tyranny, oligarchy and ochlocracy (or, frequently, again democracy), where rule was arbitrary rather than directed by the principle of the good of the city. Nevertheless, one root idea of a republic, that of common interest and participation, was present in the contrast between Greek city-state and barbarian empires, with their irresponsible rulers and submissive mass of subjects.

In any event, republic, when applied to ancient governments, has implied some popular and collective power and the absence of hereditary or autocratic rule, as contrasted with government by kings or emperors.

The modern usage of "republic" derives from these dual ideas, absence of monarchy, and some degree of avowed concern for the common welfare of the state and for public control or participation. During the later middle ages there were established some brief-lived local republics, consequent on revolt. But it was in certain city-states of Italy during the Renaissance, of which the most celebrated are Venice and Florence (during a limited period after the expulsion and before the return of the Medici) that the republic re-emerged as a meaningful designation and form of government. Here again absence of monarchy, of an established lordly ruling family or of a self-imposed absolute ruler was the first test. In such republics a share in control of government was often confined to noble or wealthy privileged families, while the form of government tended to be by a small group, co-opted or elected on a narrow franchise, though sometimes with a titular head of state, such as the doge in Venice. On occasion, too, as a result of popular pressure or revolt, government might for a while come to rest on a broader base, and to include representatives of at least the lesser burghers and the artisans.

But republics which combined the ideas of absence of monarchy, a realm of public affairs and popular consent or participation first emerged, generally as temporary phenomena, in the 17th and 18th centuries. Cromwell's commonwealth, though it developed into rule by one man not unlike the more moderate modern dictatorships, had its genesis in antimonarchical doctrines and forces, expressed in the Great Rebellion against Charles I. During that conflict, too, the concept of the interest of the community at large in government became firmly associated with the republican idea. The Dutch republic, though it was headed by a stadholder, initially the equivalent of a modern strong president, combined opposition to monarchy (and to Catholicism) with a concept of independence not unlike the later idea of national self-determination, with implications of a common collective interest and a certain degree of public participation and control. Similar considerations also played a part in the early evolution of the Swiss republic, which after many vicissitudes became the modern federal republic of Switzerland. Here, however, the independent city-states of the Reformation, republican even when theocratic and in some cases free still earlier, provided a foundation.

The antimonarchical idea constituted a major element in both the American and the French Revolutions. The former created a lasting republic, the United States of America, while the second created a temporary republic in France but firmly established the republican idea and spread it throughout most of western Europe. In both revolutions the twin ideas of consent of the governed and the rights of man played a major part. A little later the separation of the Spanish-American colonies from Spain produced numerous republics which rested on similar ideas. During the 19th century, however, the moral significance of the republican idea declined in Europe, where monarchies continued and republics remained the exception. Constitutional government spread in the monarchies, and by the early 20th century the term "republic" no longer connoted the substance and content of political institutions and practice. "Democracy" tended to supplant "republic" in describing governments free from arbitrary and imposed authority. Democracy was widespread in Great Britain (also the British Commonwealth) and the Scandinavian countries—all monarchies. In Latin America, on the other hand, nominal republics were often dictatorships on behalf of oligarchies.

In these and other instances, the term "republic" had been stripped of its earlier appeal as the alternative to divine-right monarchy and autocracy.

After World War I, the emergence of dictatorships, which might function formally within a monarchical state (Fascism in Italy), might reject the idea of a republic without restoring monarchy (Francisco Franco's Spain), though restoring the title of empire (Hitler's third *Reich*), or might continue nominally as republics, rendered the classification of regimes into monarchies or republics practically meaningless. After World War II, moreover, the term had still less relevance. The United States of America, Franco's anti-Communist dictatorship in Spain and Joseph Stalin's Communist dictatorship in the U.S.S.R. were all nominally republics. In essence, the basic classification of governments was into constitutional governments and dictatorships, a division which corresponded in ethos to the former opposition of republic and monarchy. The term republic no longer had a manifest connection with struggles over liberty, authority and sovereignty. The adjective "republican," however, was still sometimes used with connotations equivalent to its ancient meaning in political ethics.

In the United States the term "republic" has special connotations and is frequently used with supposed historical justification to contrast with democracy and as a ground for denial that the U.S. is technically a democracy. The bases for this contrast are (1) the ancient and purist use of the term "democracy" to denote small-scale direct democracy; (2) the classical fear, which continued at least to the end of the 18th century, of such democracy as unstable and fickle; (3) the Ciceronian interpretation, which widely influenced the U.S. founding fathers, of the Roman republic as a mixed and balanced government; and (4) the revival by Montesquieu in the 18th century of the idea of democracy as direct and small scale, and his insistence that democracy was impossible in a larger state, which could be at best a representative republic. These ideas were studied and combined by a number of the founding fathers, and especially by James Madison, who used the term "republic" (1) as a technical designation for representative government as opposed to direct democracy and (2) to insist on the necessity for a system of checks and balances against the dangers of straight majoritarian decision in a legislature elected by majority on a single principle of representation. The insistence that republic is not synonymous with democracy either as direct democracy or as absolute majoritarian democracy, but rather is synonymous with constitutional democracy, is correct in the specific U.S. context, though that usage is a narrowing of the wider use of the term to denote any nonmonarchical regime. The guarantee to the states of the union of a republican form of government (in a nation whose given title deliberately excluded the designation republic) seemingly refers primarily to the more generic usage and it does not imply specific forms or checks.

REPUBLIC, FUND FOR THE, a U.S. educational corporation chartered in 1952 by the state of New York "to defend and advance the principles of the Declaration of Independence and the Constitution." It was organized as an autonomous body, and the founding grant of $15,000,000 from the Ford Foundation was terminal.

In 1954 Robert M. Hutchins (*q.v.*) became president of the Fund, succeeding Sen. Clifford P. Case of New Jersey, who had resigned to run as Republican candidate for the U.S. Senate.

The Fund's concerns included restrictions and assaults upon academic freedom, due process, equal protection of the laws, and the rights of minorities; the use of censorship, boycotts, and blacklists by private groups; and the increasing exercise and acceptance of the principle of guilt by association. The Fund, in its first five years, acted as a grant-making foundation to support educational activities of civic and religious groups that opposed restrictions and infringements of civil rights and civil liberties. Among these were the Southern Regional Council, the American Friends Service Committee, the Anti-Defamation League, the National Urban League, the Legal Defense and Educational Fund of the National Association for the Advancement of Colored People, the National Council of Churches, and the interracial programs of major religious denominations and of the YMCA and YWCA.

The Fund also financed research in the areas of civil rights and civil liberties. Its largest single appropriation, $465,000, was for the preparation and publication of a definitive 15-volume study, directed by Clinton Rossiter, on Communist influence and control in the United States. Examples of the Fund's actions to bring relief to victims of civil rights and civil liberties crises were John Cogley's study of blacklisting in industry—especially the entertainment industry—and reports by Adam Yarmolinsky on the federal government's loyalty-security program and by Paul Lazarsfeld, Wagner Thielens, Jr., and David Riesman on the intimidation of teachers.

After two-thirds of the Fund's capital had been expended, its program was redirected toward clarification of the basic issues "involved in maintaining a free and just society under the strikingly new political, social, economic, and technological conditions of the second half of the twentieth century."

The Fund in 1959 established as its sole activity the Center for the Study of Democratic Institutions at Santa Barbara, Calif., for the purpose of focusing a variety of informed, frequently conflicting viewpoints on significant social, economic, political, and cultural issues in relation to democratic institutions.

The Center set up a small resident staff with permanent and special consultants. In one 12-month period, its visitors included 246 persons from 42 countries who met with the residents and consultants in their daily discussions and debate of specific issues; the resulting papers—often including dissenting comment—were published. In its first five years the Center distributed more than 5,000,000 copies of its publications to interested persons for use in classrooms and in the educational programs of business, union, and church groups. Many of the publications stimulated editorial comment and were reprinted, reviewed, and discussed in other publications; more than 75 books and hundreds of magazine articles were developed from the Center's materials or as products of Fund grants; and over 3,000 tape transcripts of Center discussion programs were made available to radio stations and to universities and adult education groups. The Center's principal contribution was to promote discussion, analysis, and argument of "those aspects of contemporary issues which are usually neglected, misunderstood, or obscured by the smoke of controversy."

REPUBLICAN PARTY (U.S.), one of the two leading political parties in the U.S. since the 1850s. The party originated in 1854 when various small group meetings, the earliest in Ripon, Wis., were held in a half dozen states. A mass meeting at Jackson, Mich., attended by former Whigs, Democrats, and Free-Soilers on July 6, 1854, adopted the name Republican. This was an appealing title not only for those who recalled Jeffersonian "republicanism," but for those who placed the national interest above sectional interests and were opposed to states' rights. The issue presented by slavery in Kansas had called this party into existence. It was from the beginning strongly nationalistic. The pronouncement that slavery was a moral, social, and political evil was coupled with denunciation of the Kansas-Nebraska legislation and the Fugitive Slave law.

An informal meeting in Pittsburgh, Pa., on Feb. 22, 1856, planned the first national convention, which assembled in Philadelphia, Pa., on June 17. Its platform denied to congress the right to recognize slavery in a territory, and held that congress had the right to abolish slavery in the territories and ought to do so. This view, no longer that of extremists, was representative of widespread sentiment in the north. John C. Frémont, who was widely known for his western exploration and in 1849 had been elected to the senate from the state of California, was the party's nominee for the presidency. He won 114 electoral votes, but was defeated in a three-cornered contest against Millard Fillmore, candidate of the American ("Know-Nothing") and Whig parties, and the cautious and conservative Democrat, James Buchanan, who was elected.

Lincoln and Civil War.—During the next four years the nation drifted toward civil war. On May 16, 1860, the Republican national convention met in Chicago, Ill., and nominated Abraham Lincoln. In a four-party contest, Lincoln led the Republicans to victory. (*See* UNITED STATES [OF AMERICA]: *History.*) The new party had rapidly displaced the Whigs in the north as the main opponent of the Democrats.

Lincoln's primary policy was the preservation of the union. The outbreak of rebellion in southern states and the secession of 11 states played havoc with existing party lines. For four years the armed conflict came to no positive conclusion. In the autumn of 1864 the president faced the necessity of going to the people at the stated election time, and did so with slight hope of a vote of endorsement. His supporters confessed their weakness. In calls for a convention and in the convention, they termed themselves the Union party. This party, with Lincoln as its nominee and a war Democrat, Andrew Johnson, as vice-presidential nominee, did defeat the Democrats who had in their national convention that year declared the war a failure. The war was continued to a successful conclusion, but the assassination of Lincoln, who died on April 15, 1865, brought a complete realignment of political forces.

Reconstruction and After.—Within a year of the end of hostilities, the Republican party had reappeared and was functioning as an organization bent upon retaining control of the government and taking a form that was to prove the most powerful yet seen in the history of parties in the United States. Throughout the following 30 years, the Republicans and the Democrats—who by the autumn of 1866 appeared as the one agency of strong opposition—fought for control of the national government, the Republicans usually winning.

The fight for improvement in the civil service, for genuine tariff revision, for a democratic land policy and for protection of the Indians persisted within the parties. Within the Republican party, insurgent groups protested in vain at the rigidity of party control. On two occasions such groups left the party, the Liberal Republicans in 1872, and the Progressives in 1912. Yet on each occasion many leaders and millions of voters remained.

In the years of chaotic reconstruction, the Republicans kept troops in the south and attempted to confer political power upon the unprepared Negro. In these years the Republican party organization was revealed as of selfish design and cowardly practice, ruled by a small and usually self-perpetuating group of politicians who made party regularity a fetish. Their list of nominees for the presidency included Generals Ulysses S. Grant, Rutherford B. Hayes, James A. Garfield and Benjamin Harrison, and Maj. William McKinley. To the support of these tickets rallied voters from the villages and country districts of the old east and of the new west, mostly men of small means attached to the traditions of their pioneering forefathers. The Republican appeal was frankly to businessmen as the 19th century ended.

The tariff was included in the Republican platform as an issue in the campaign of 1896, but as election day approached much greater prominence was given the question of the free and unlimited coinage of silver. William McKinley of Ohio was nominated by the Republicans on a gold standard platform and won the election.

Republicans in congress had in 1896 favoured recognition of the independence of the Cubans, who were in revolt against the government of Spain. The Republican party platform of that year expressed the hope that the Cubans would win their struggle for liberty and that the U.S. government would actively use its influence to restore peace and give independence to the island. In April 1898 President McKinley, responding to public opinion inflamed by the sinking of the battleship "Maine" in Havana harbour, demanded that Spain withdraw from Cuba. War came soon after, a war that for many months had seemed to members of both parties desirable and inevitable. The war nevertheless exposed issues in world relations that led to a sharp division between the two parties. A treaty of annexation of the Hawaiian Islands had been negotiated by Pres. Benjamin Harrison in 1893 and withdrawn by Pres. Grover Cleveland. The Republicans, who came to favour such annexation, argued military and commercial necessity. Despite strong Democratic opposition, in the summer of 1898 by joint resolution of congress the republic of Hawaii was annexed to the United States with territorial status.

The nation entered upon the congressional campaign of 1898 before the end of the war with Spain. The Republicans gained 8 seats in the senate, although the Democrats gained in the house by 29. The administration now called for the cession of the Philippines to the United States, and Spain was forced to yield.

Early 20th Century.—A new era in Republican party domination was dawning. Theodore Roosevelt, who in 1898 had been elected governor of New York, was supported for the vice-presidency in the campaign of 1900 by Republican party boss T. C. Platt, who was anxious to get him out of New York politics. Roosevelt had a large and enthusiastic following among the delegates from western states, and was nominated against the wishes of both McKinley and Marcus Alonzo Hanna, who, however, bowed to the will of the convention. The problem of the party managers was one of first magnitude when, in the autumn of 1901, the assassination of President McKinley brought to the presidency the independent and imaginative Roosevelt. Since the Republican party at that time did not possess a definite party program, as it had in 1897, there was both opportunity and need for a leader who could reshape its appeal and its purpose. This President Roosevelt proceeded to do.

In considering the course of action that should be his at this juncture, Roosevelt chose to direct his attention to the trusts that had become extremely powerful. The president's attack was directed not upon large business, as such, but upon business combinations that believed themselves superior to the government. The popularity of Roosevelt's position on the trusts and his aggressive action in the coal strike of 1902 brought to his support thousands who had for many years been interested in governmental control of corporations.

Roosevelt's acquisition of the widespread popular support that won him re-election in 1904 was made possible by the failure of the Democratic party to justify the expectations aroused in 1896. The party had seemed at that time to promise emancipation from the oppressions of organized wealth and millions of voters had twice supported William Jennings Bryan for these reasons. When Roosevelt professed to desire the same ends, many Democrats came to his support.

The overwhelming endorsement of Roosevelt in 1904 gave to his second administration a more personal character than had prevailed in the preceding three years. That Roosevelt subsequently brought about the nomination of William Howard Taft, who was elected in 1908, led to a widespread but erroneous belief that the Republican party organization was responsive to Roosevelt's leadership. With the overthrow in 1910 of their majority in the house of representatives, the Republicans ended 14 years of complete control of the national government. The 1910 elections also revealed the strength of western party insurgents who henceforth opposed the national party on many issues.

Republican Presidential and Vice-Presidential Nominees
(Successful candidates in boldface type; unsuccessful in lightface type)

Year	Presidential nominee	Vice-Presidential nominee
1856	John C. Frémont	William L. Dayton
1860	**Abraham Lincoln**	**Hannibal Hamlin**
1864*	**Abraham Lincoln†**	**Andrew Johnson**
1868	**Ulysses S. Grant**	**Schuyler Colfax**
1872	**Ulysses S. Grant**	**Henry Wilson†**
1876	**Rutherford B. Hayes**	**William A. Wheeler**
1880	**James A. Garfield†**	**Chester A. Arthur**
1884	James G. Blaine	John A. Logan
1888	**Benjamin Harrison**	**Levi P. Morton**
1892	Benjamin Harrison	Whitelaw Reid
1896	**William McKinley**	**Garret A. Hobart†**
1900	**William McKinley†**	**Theodore Roosevelt**
1904	**Theodore Roosevelt**	**Charles W. Fairbanks**
1908	**William Howard Taft**	**James S. Sherman**
1912	William Howard Taft	James S. Sherman‡
1916	Charles Evans Hughes	Charles W. Fairbanks
1920	**Warren G. Harding†**	**Calvin Coolidge**
1924	**Calvin Coolidge**	**Charles G. Dawes**
1928	**Herbert Hoover**	**Charles Curtis**
1932	Herbert Hoover	Charles Curtis
1936	Alfred M. Landon	Frank Knox
1940	Wendell L. Willkie	Charles L. McNary
1944	Thomas E. Dewey	John W. Bricker
1948	Thomas E. Dewey	Earl Warren
1952	**Dwight D. Eisenhower**	**Richard M. Nixon**
1956	**Dwight D. Eisenhower**	**Richard M. Nixon**
1960	Richard M. Nixon	Henry Cabot Lodge
1964	Barry M. Goldwater	William E. Miller

*Officially the Union Party (*see* text). †Died in office. ‡Died a week before election day; his electoral votes were cast for Nicholas Murray Butler.

In Feb. 1912, Roosevelt announced that he was willing to accept the Republican nomination, thus attempting to obtain what he seemed to have in 1908, but which he had never won in open competition—control of the party machinery. He now attempted to make the party organization responsive to the demands of the party's voters. State primary elections revealed the popularity of his candidacy, but Taft won the nomination at the party convention. Roosevelt's supporters thereupon bolted the party and organized the Progressive party (*q.v.*) with a platform calling for a change in political machinery and an aggressive program of social legislation. The Progressives nominated Roosevelt for president and Gov. Hiram W. Johnson of California for vice-president. With the Republican vote thus split, the Democratic candidate, Woodrow Wilson, was elected.

At the end of World War I the Republicans returned to power, electing Sen. Warren G. Harding of Ohio as president. When Harding died in Aug. 1923 he was succeeded by Vice-Pres. Calvin Coolidge. By this time the Republican party had become more than ever a coalition of sectional leaders and divergent economic interests. Its outstanding national figures were not regulars but insurgents such as Sen. Robert M. La Follette of Wisconsin, who led his followers out of the party in 1924. In the three-party election of that year Coolidge rode to victory on a wave of prosperity that continued until after the election of Republican Herbert Hoover in 1928. An engineer by profession, Hoover had gained widespread recognition for his service as administrator of U.S. relief abroad at the end of World War I and as secretary of commerce under Harding and Coolidge. The world-wide depression that overtook the U.S. economy in 1929, and defections by Republicans in congress, led to Hoover's defeat in 1932 by Franklin D. Roosevelt. Roosevelt's three re-elections, the succession of Harry S. Truman upon Roosevelt's death and Truman's election in 1948 kept the Republicans in a minority position for 20 years.

Since 1950.—In 1952 with the nomination of a popular World War II general, Dwight D. Eisenhower, the Republican party returned to power under the dominance of its liberal-moderate wing, as opposed to its conservative wing led by Sen. Robert A. Taft of Ohio. Eisenhower's moderate course in domestic and foreign affairs attracted much non-Republican support and in 1956 the Republicans renominated him and his vice-president, Richard M. Nixon of California. Eisenhower easily defeated the Democratic candidate, former Gov. Adlai E. Stevenson of Illinois, for the second time. The Republicans failed to win control of either house of congress and in 1958 lost more congressional seats.

In 1960 the Republicans nominated Nixon for president and Henry Cabot Lodge, U.S. ambassador to the United Nations, for vice-president. Both vigorously defended the Eisenhower record and emphasized U.S. diplomatic gains and domestic advances. A major feature of the campaign was a series of joint television appearances by Nixon and Sen. John F. Kennedy of Massachusetts, the Democratic candidate. In the election, which resulted in the closest popular vote in the 20th century, Nixon and Lodge were defeated. This defeat, followed in 1962 by failure to make substantial gains in congress, widened the breach between conservative and liberal Republicans. The conservatives, former supporters of Senator Taft and younger dissidents who felt the principles of the party had been compromised by the liberal-moderate wing, came under the leadership of Sen. Barry M. Goldwater of Arizona. The liberal-moderates, concentrated mostly in the eastern and northeastern U.S., were divided, looking for leadership to such men as Nixon, Lodge, Gov. Nelson Rockefeller of New York, Gov. George Romney of Michigan and Gov. William Scranton of Pennsylvania.

The conservatives, with superior organization at the grass-roots level, dominated the 1964 national convention, although Goldwater had won only one important primary, in California. The liberals and moderates were unable to unite effectively behind any one candidate, and Goldwater was nominated on the first ballot. For his running mate he chose Rep. William E. Miller of New York, the Republican national chairman and, like Goldwater, a militant conservative. Goldwater made no concessions to the moderates in his acceptance speech, and shortly after the convention he filled the strategic posts in the national organization with conservatives of his choice, many of them new to national politics.

Some moderates, including Eisenhower, Nixon, and Scranton, eventually endorsed him, but other Republican candidates concentrated on their own campaigns, giving little or no support to the national ticket. During the campaign Goldwater and Miller denounced the trend toward centralized government under Democratic administrations and urged greater firmness in opposing Communism abroad. Their campaign strategy was based on exploiting the presumed discontent of many voters with current developments in American society, including the opposition of normally Democratic white southerners to the civil-rights policies of the Kennedy–Johnson administration.

The election on Nov. 3 was an overwhelming Democratic victory, the Republican national ticket carrying only Arizona and five states of the deep south. The Johnson landslide cut across all levels of government, bringing with it large Democratic majorities in congress and in state legislatures throughout the country. In many instances the Republican candidates who won or who ran significantly ahead of the national ticket were those who had dissociated themselves from Goldwater.

With the party's fortunes at their lowest point since 1936, Goldwater's appointees were removed from the national organization and Ray Bliss of Ohio, an astute organizer not identified with any particular faction, was named as national chairman. Bliss's announced intention was to intensify Republican appeals to urban and ethnic groups, largely ignored during the 1964 campaign. However, the party's organizational and financial efforts continued to be splintered among a number of more or less independent factional groups, such as the liberal Republicans for Progress and the conservative Free Society association, which Goldwater helped to found.

In the 1966 elections the party showed strength, capturing 8 governorships, to give it a total of 25 out of 50; 3 new seats in the senate; and 47 additional seats in the house. Although it is normal for the party out of power to make gains in mid-term elections—and the Republicans were left still short of a majority in either house of congress—the party gained in national power and in prestige.

REQUESTS, COURT OF, in England, one of the prerogative courts (*q.v.*), was a minor court of equity, in origin a committee of the King's Council, presided over by the lord privy seal. Its records begin in 1493. It followed the king until established at Whitehall in 1516 or 1517 by Cardinal Wolsey, and until about 1529 it was called the Court of Poor Men's Causes. A popular court because of the lesser expense involved, it dealt chiefly with matters such as title to land, covenants, annuities, forgery, and debt.

Two permanent masters of requests were appointed about 1550 and four in 1603; the link with the council was gradually forgotten. From 1590 onward a series of prohibitions from the Court of Common Pleas reduced business in the Court of Requests. It was not abolished in 1641 with the other prerogative courts, but the masters ceased to sit after 1642 and appointments made after the Restoration of Charles II (1660) were only for the purpose of assessing compensation due to royalists.

The name courts of requests was also given to inferior local courts established by special act of Parliament to deal with small debts. These courts were abolished by the County Courts Act (1846). The City of London's Court of Requests, often called the Court of Conscience, was abolished in 1847.

See I. S. Leadham, *Select Cases in the Court of Requests* (1898); J. R. Tanner, *Tudor Constitutional Documents* (1922).

RESCUE MISSION (GOSPEL MISSION), an institution designed to administer spiritual and physical succour in city slums. It originated in the city mission movement among evangelical laymen and ministers early in the 19th century. David Nasmith, a Scottish philanthropist, was instrumental in founding the Glasgow City Mission (1826) and the London City Mission (1835), both of which sought to evangelize and rehabilitate the urban poor. Beginning with home visitation and tract distribution by volunteer lay missionaries, the city mission movement expanded into Sunday school, day school, and temperance activities with paid missionaries, and eventually provided food, lodging, employment, and medical care to the destitute and sick.

In 1848 Johann Wichern, a German Sunday school worker, founded the Hamburg Society for the Inner Mission which coordinated church and charitable activities in Hamburg and later spread throughout Germany. The New York City Mission and Tract Society began home visitation in the 1830s and founded its first mission station in 1852. The work of William Booth and the Salvation Army (*q.v.*) after 1865 brought a new impetus to rescue mission endeavour.

Most rescue missions have been founded and supported denominationally or interdenominationally, but some of the most successful have been nondenominational, among them the North End Mission in Boston (1867), Jerry McAuley's Water Street Mission in New York (1872), and Col. George Clarke's Pacific Garden Mission in Chicago (1877). Although the work of rescue missions resembles that of settlement houses (*see* SOCIAL SETTLEMENTS), institutional churches, and charitable societies, it is distinguishable from these by its emphasis upon religious conversion through evangelistic preaching services.

RESEARCH, INDUSTRIAL, is research undertaken on problems related to industrial products or production methods. Traditionally it stood in contrast to fundamental or basic research carried on without regard for its immediate practical value, but with increasing government financing of research projects the contrast between industrial research and fundamental research has lessened considerably. In the middle years of the 20th century industrial research also extended its scope to include the systematic study of industrial operations, the handling of materials, and the

layout of plants. As it became concerned broadly with the economic efficiency of industry it contributed to raising the level of productivity through the better use of human and material resources.

In the early days of industrial research an individual inventor would present his idea to a producing firm in the form of a model, which had then to be redesigned by the firm's engineers if it were to be made suitable for industrial production. (*See* INVENTIONS AND DISCOVERIES.) The process, while yielding good results in the long run, was slow, haphazard, and wasteful. From about the beginning of the 20th century, therefore, industrial firms began to employ men who were trained in scientific methods, most of whom were drawn from the universities. These men worked independently on individual projects, with or without assistants. But as projects became more complex they could not be completely carried through by a single researcher and had to be tackled by research teams. The increasing scale of industrial research led throughout the world to its concentration into ever bigger units, controlled by large organizations or groups of companies. The importance of its results led to increasing government interest in it; and by the 1960s many countries were supporting industrial research projects with government funds. A striking feature of modern industrial research is the degree to which countries such as the United States and the U.S.S.R., with their profound differences of ideology and of organization, have relied upon government financing.

Many problems are so vast that they have to be tackled internationally as, for example, with the union of smaller nations in joint scientific projects such as the European Atomic Energy Establishment, and even by collaboration between the United States and the U.S.S.R., as in the International Geophysical Year of 1958. This international network produces a type of organization with complex scientific instruments, libraries acting as memory stores, and elaborate communications systems. In this last field lies the greatest handicap to smooth growth. The very mass of scientific data being processed all over the world may clog the machine; the accumulated knowledge in the libraries of the world is recalled very erratically and a considerable portion is forgotten forever and has to be rediscovered. This problem was being investigated the world over in the 1960s.

There is no way of evaluating the results of research in terms of accountancy. Most good industrial research laboratories can point to some outstanding achievements over a period of years and claim rightly that if they had done nothing else they would have paid for themselves handsomely. But although this may inspire confidence it does not enable a board of a company to determine how much of its profits it should devote to research. Research expenditure in industry is frequently expressed as a proportion of annual turnover, and the proportions, as would be expected, vary greatly from industry to industry (3% is not uncommon in firms in the newer science-based industries). There is, however, no logical justification for comparing or estimating research expenditure on this basis; experience and judgment are the only guides, and boards of companies who are alive to the needs of the times endeavour to maintain a level of research which will enable them to remain competitive in world markets. (A. G. Fo.)

UNITED STATES

In the United States, as elsewhere, research and development had, by the middle of the 20th century, gained recognition as significant factors in economic growth and national security. This had, of course, not always been the case. In the early 1900s a few large firms had organized research departments but, in the main, these had grown out of the work of private inventors like Thomas A. Edison (1847–1931), who were formally associated with particular companies. Before 1900 technological advance depended solely on the skills of individual inventors and upon the industrialists who were prepared to make use of their discoveries. The patent system was specifically referred to in the U.S. Constitution of 1789 but during the following century few industrialists realized that they could emulate early inventors and increase their profits by contributing to the research and development process. There was, in fact, much misunderstanding between scientists and industrialists, and many businessmen strongly doubted the wisdom of operating research departments within their industrial organizations. It was only at the beginning of the 20th century that the drawing office started to evolve into the engineering department and test house, and then into the research laboratory. World War I did much to call attention to the benefits that could be gained by the systematic application of scientific methods and discoveries to industrial problems; and after the war many companies regarded research as an integral part of their business activities.

Between the World Wars.—Reliable statistics on the extent and character of industrial research in the United States are virtually nonexistent for the period before World War II, but figures compiled by the National Research Council suggest that there was a sevenfold increase in the industrial research effort during the period 1920–40. In 1920 about 300 industrial companies employed 9,300 research workers, and by 1940, 2,350 companies were employing more than 70,000 workers. The expenditures by industrial companies for research in 1940 were thought to be about $300,000,000 a year. Industrial research was still confined mainly to the large corporations, but smaller companies were beginning to appreciate its influence on their business operations.

The number and size of industrial research laboratories grew steadily, and their importance began to rival that of government research establishments. After World War I, the government could have taken the lead in organizing the development of industrial research, as in Great Britain; but the strong desire for economy and tax reductions resulted in the government's leaving the bulk of industrial research to the large industrial corporations. Nevertheless in the Department of Commerce there was a strong link between the government and industrial research, which had grown out of the need for effective governmental control of weights and measures and of standardization in general. The secretary of commerce (1921–28), Herbert Hoover, who had begun his career as a mining engineer, was one of the few major political figures of his time who had a true appreciation of the value of science. He believed that his department should carry out scientific research and should also help to eliminate inefficiency from industrial operations. Under his guidance the National Bureau of Standards worked with industry to launch a cooperative program of simplified practices and commercial standardization; and by 1924 about 23 industrial trade associations were supporting 29 research associates, who worked alongside government scientists at the National Bureau of Standards. Hoover appreciated the dependence of industrial research on fundamental research, and he was also well aware of the paucity of American fundamental research at that time. Believing that industry should bear some responsibility for fundamental research, and in an effort to redress the balance, he was instrumental in establishing the National Research Fund in 1926. This fund was designed to allow industry to make regular and substantial contributions to a monetary pool to be used as a common source of finance for universities carrying out independent fundamental research. For a variety of reasons the fund was a failure and was discontinued in 1934; but it marked a realization that both government and industry had a responsibility for maintaining a balance between pure and applied science.

The depression years (1929–38) resulted in substantial reductions in the research activities of both government and industry. At the same time the government undertook a detailed examination of the function of research within the national economy. This led to the modern concept of research as a vital national resource, and a recognition of government responsibility for the total national research effort. As a result, from 1935 onward, the federal government played a larger and larger part in national research activities, a trend which was accelerated by the demands of World War II.

After World War II.—Many of the characteristics of wartime research effected permanent changes both in research itself and in the relations between government and industry. By 1961 the government had become the principal source of funds; but because the perpetuation of the wartime research contract system resulted in the expenditure of most of this money in industry, industry be-

came responsible not only for research designed to improve its own products and methods, but also for a major proportion of military research. This, far from being a handicap, enabled U.S. industry to build up larger and more versatile research facilities than those of any other country.

The rapid and spectacular growth in federal research and development in the decades following World War II tended to disguise the equally significant growth in nonfederal research activity —a ten-fold increase between 1941 and the early 1960s. There is no single reason for this great expansion in privately sponsored research. In addition to the evidence provided by World War II of the value of research, there was the effect of taxation policies, and also the rapid expansion of training facilities at academic institutions, which helped to make society more research-conscious.

In 1961 the aircraft industry and the electrical industry together accounted for nearly three-fifths of the $10,900,000,000 spent on industrial research and development. This heavy concentration of activity arose because of the large numbers of government-sponsored projects in such fields as rocketry, electronics, and atomic energy. Next came the chemical and allied industries which spent $1,100,000,000, and then the transport industry with an expenditure of $896,000,000. In nearly all industries, the bulk of research and development was undertaken by firms employing more than 5,000 persons; and in several industries; *e.g.*, aircraft production and oil refining, more than nine-tenths of it was conducted by large firms. Although nearly all industrial research was financed by the government and by companies, a relatively small amount was financed from "other sources" (which spent $79,000,000 in 1961). These included commercial and nonprofit organizations providing an extensive range of specialized services for industrial firms on a contract basis.

Of the nonprofit-sponsored research institutes that have long played an important role in industrial research in the United States, the Mellon Institute, Pittsburgh, founded in 1913, is typical. It is an endowed, nonprofit, corporate body "for conducting comprehensive investigations on important problems in the fundamental and applied natural sciences, for training research workers and for providing technical information adaptable to professional, public and industrial advantage." There being no need to consider owners or shareholders the institutes have complete freedom to choose their program. They are free to pay their workers at the current market rates; and, as they are not hampered by conditions of academic tenure or by civil service regulations, they can employ staff on short-term contracts. This flexibility enables them to respond rapidly to the changing research needs of their sponsors, and thus contributes toward their effectiveness. Methods of operation are varied. First, an institute can perform a complete investigation for a sponsor, providing the same service as a central research laboratory does for its company. It is often only by recourse to an institute that a small company can afford to undertake any substantial research, which increasingly demands the facilities of a large and expensive laboratory and the combined efforts of a team of highly qualified scientists and engineers. Large firms, too, often use institutes when they do not wish to disrupt their current activities, or when they require special extra skills and facilities. Second, a sponsored research institute can provide valuable training for graduates, who will eventually be employed by the sponsor company. Third, many of the institutes can use funds of their own for investigations of their own choice. For example, by 1962 about 55% of the total contract research undertaken by the Armour Research Foundation was the result of its own efforts to build up specialized knowledge in particular areas selected by its staff. About 30% of its 650 then-current sponsored projects had stemmed from ideas generated by the staff and had been subsequently taken over by suitable sponsors.

Numerous universities, too, undertake sponsored research for industry in much the same way as the nonprofit and commercial research institutes. When research on specific problems is required, special arrangements can be made to safeguard the "rights" of the sponsor, and the results can remain secret for an agreed period. Generally, however, educational institutions prefer to accept research contracts only when the freedom of action of their workers can be maintained; and it is increasingly recognized that industry has a responsibility to support fundamental research on an unrestricted basis and that this should preferably be carried out in a university or college. This has led to the development of industrial research fellowships and industrial grant-in-aid schemes for the support of long-term basic research programs in universities, with few restrictions on the field of work, which is often selected by the universities themselves.

An interesting development took place in 1963 when the Carnegie Institute of Technology, the University of Pittsburgh, and the Mellon Institute jointly set up the MPC Corporation to enable them to collaborate on scientific and educational studies. A major aim of the corporation is to stimulate collaboration between its constituent institutions and local industry.

Another type of nonprofit research institute is the federal contract research centre, which had its origin in technological operations conducted by the Office of Scientific Research and Development (OSRD) during World War II. OSRD was empowered, among other functions, to coordinate and supplement research activities for the public good, and in this capacity it created by contract what are in effect national research laboratories to undertake projects demanding unusual equipment or special skills such as, for example, projects on radar and proximity fuses. After the termination of OSRD in 1947, responsibility for the Federal Contract Research Centres passed to a variety of other government agencies, and later on a number of other facilities of the same type were set up. By 1963 there were 60 such centres, together absorbing $1,300,000,000—or about 10% of all federal funds spent on research and development during that year. The 19 centres administered by industrial companies spent about $440,000,000 per annum in the early 1960s. The majority of these centres were concerned with large-system engineering projects in such fields as electronics, space research, and atomic energy. The Jet Propulsion Laboratory, for example, was administered by the California Institute of Technology on behalf of the National Aeronautics and Space Administration, and was concerned with the development of unmanned interplanetary spacecraft and related technology. Although administered by an educational institution, much of its work (which cost about $300,000,000 in 1962) was subcontracted to industry.

The end results of industrial research are new and improved products and processes. But it has long been realized that no one company or industry could afford to undertake all the research that might be relevant to its business. Of more and more importance has become the task of providing information to guide the wise formulation of research programs and the selection of development projects on a basis of comprehensive knowledge of the results of current and previous work elsewhere. Scientists have always realized the importance of such information; but only after about 1950 was information recognized as a vital industrial research tool, and systematic attempts to improve national and company information services date from then. Thus emerged the specialized information centre, whose task is to collect, assess, and consolidate information in a narrow field, and to disseminate it to potential users. By the middle 1960s there were more than 200 such centres operating on a national basis. The majority were financed with federal funds, but some were financed on a co-operative basis by groups of companies, and others were operated by universities and scientific societies. Large companies, too, recognized the importance of the centres, and some had established them within their research departments in much the same way as laboratory equipment. (Ed. G. H.)

GREAT BRITAIN

The government role in industrial research first became important in Great Britain during World War I, which led to the setting up of the Department of Scientific and Industrial Research (DSIR) in 1916. In 1918 this department became financially responsible for the National Physical Laboratory, which had been established in 1900 by the Royal Society with a small treasury grant. The department grew steadily, and by 1939 it had a net annual expenditure of £500,000. World War II hastened its de-

velopment so that by 1960 it was spending more than £8,000,000 yearly. Increasing government awareness of the importance of industrial research and the need to encourage postgraduate work in universities led to even faster expansion, so that annual expenditure by the mid-1960s was rising above £20,000,000.

The work of DSIR is carried out in 15 research establishments of its own and in more than 50 autonomous industrial research associations to which it makes grants. It also contributes to research at universities and colleges and makes awards to postgraduate students. The DSIR's own laboratories tend to concentrate on work of national importance which no one private industry can undertake; *e.g.*, road research, water pollution research, geological survey, building research, and chemicals research.

The research association scheme, by which the government financially assists groups of firms with similar interests to carry out research in collaboration, was started in 1917. By the mid-1960s more than 50 associations had a total annual income of approximately £8,000,000 (compared with £5,000,000 in 1955); less than a quarter of this being contributed by the government with the advice of the Industrial Grants Committee of DSIR. More than 60% of industry is able to make use of associations, from the large British Iron and Steel Research Associations (BISRA, annual income, £1,000,000) to the much smaller File Research Council (annual income £12,000). Among the largest associations are those for the metal industry, electrical engineering, marine engineering, and shipbuilding.

The research associations are autonomous and are governed by councils mostly drawn from industry, but with DSIR representation. The councils are responsible for research programs on which they have the advice of committees consisting of members of industry and often of university or government scientists or trade union representatives as well. The DSIR appoints two visitors to each association; usually a scientist and an industrialist. Commonwealth and other overseas manufacturers are often members. The associations provide bulletins, technical reports, lectures, films, training classes, exhibitions, and mobile demonstration units for their member firms.

The nationalized industries have their own research organizations. The National Coal Board has three centres; the electricity supply industry and the Gas Council have each three principal laboratories.

Nuclear energy research and development is carried out by the Atomic Energy Authority (AEA; set up by the Atomic Energy Authority Act, 1954) under the minister for science. Although the AEA is free from day-to-day government control, most of its income is from public revenue. The AEA produces explosive nuclear material, carries out weapon research for the armed services, and builds the prototypes of nuclear power stations for civil use. Various government committees coordinate research on nuclear power for ships and on the health and safety aspects of work with atomic energy.

Space research is coordinated by the minister for science, with the advice of other ministers and of a steering group representing government and university scientists. This group is advised by the British National Committee on Space Research, which the Royal Society appoints, and which also represents the United Kingdom internationally in, for example, the Special Committee on Space Research (established in 1958 by the International Council of Scientific Unions). The practical work is done at universities (to which DSIR directs grants) and government research establishments. Equipment and materials also are developed by private industry. Government expenditure was estimated at more than £1,000,000 in 1963.

The dissemination of the results of research to other workers and to users in industry is difficult because of the rapid increase in the amount of information available. The time lag between the discovery of scientific or technological facts and their industrial application grows constantly. Therefore, while the traditional publication of papers is still carried on, other means of dissemination are utilized, such as the establishment by the government of technical liaison centres in industrial regions to help in channeling inquiries from industrialists to research workers. The research associations also try many ways of improving communications between their scientific staff and industry; while firms themselves have established technical information departments within, or parallel with, their research and development departments. The need for qualified staffs to run these departments resulted in the establishment in 1958 of the Institute of Information Scientists, a qualifying body which sponsors postgraduate training and research with the help of a DSIR grant.

DSIR also supports ASLIB (the Association of Special Libraries and Information Bureaux); and has set up a National Lending Library for Science and Technology (1961). In collaboration with the National Science Foundation of the United States, this library makes available foreign works, particularly Russian and Chinese, in translation.

By 1964, scientific policy was a major item in electoral programs of political parties, and a major reconstitution of the government departments dealing with science, and probably of the DSIR also, seemed likely as a result of the implementation of the report (1963) of the committee of inquiry into the organization of civil science set up in 1962 under the chairmanship of Sir Burke Trend. (A. G. Fo.)

U.S.S.R.

In the U.S.S.R. the organization of scientific research, including industrial research, is very different from its organization in non-Communist countries. The scientific activity itself, if the social sciences and biology are excluded (and therefore this applies virtually to the whole of industrial research), is much the same in the Soviet Union as elsewhere. Developments are taking place along similar lines in all parts of the world, although, inevitably, differences exist as to the rate of progress, which depends on resources and on the degree of priority or importance attached to various fields in various countries. The broad objectives also are similar in many ways. A comparison of the aims, in the field of scientific research, of the Communist governments with those of Western governments, for example, has revealed many similarities. But the organization of research could hardly be more different.

The Role of Scientific Research.—In the U.S.S.R. science is called upon to play a decisive role. This has been so ever since Lenin in 1918 called upon the Academy of Sciences to organize committees of specialists who would draw up a plan for the reorganization of industry on a basis of the formation of large enterprises. The aim was to make the Russian Soviet Republic largely independent of the outside world for its raw materials and industrial products. An important factor in the achievement of this aim was to be electrification.

The extent to which science is allowed to lead a life of its own independently of the needs of industry has varied. Under Stalin, there was great emphasis on the need to solve industrial problems, often short-term ones, at the expense of basic or long-term research. After Stalin's death in 1953, however, fundamental research became more acceptable officially, and although science was still considered valid only within the philosophical confines of Marxism-Leninism, the pressures on scientists to reject spheres of work (*e.g.*, relativity theory or cybernetics) on ideological grounds were greatly lessened.

As a result of the view of science as a powerful force for the development of the economy, an important feature of Soviet industrial research is the continuing effort through exhortation and legislation to "strengthen the ties between science and production." The program adopted at the 22nd Congress of the Communist Party on Oct. 31, 1961, describing the "tasks of the Communist Party of the Soviet Union in building a communist society," began the section *Tasks in the Field of Science* with the assertion that, under the socialist system of economy, scientific and technical progress enables man to employ the riches and forces of nature most effectively in the interests of the people; and ended it with the sentence: "It is a point of honour for Soviet scientists to consolidate the advanced positions which Soviet science has won in major branches of knowledge and to take a leading place in world science in all the key fields."

Research Institutes.—It is difficult to draw a line between in-

dustrial and nonindustrial research in the U.S.S.R. All organizations engaged in civil research can be said to a greater or lesser extent to be carrying out industrial research. A number of categories of research organization can be described, however. First there is the Academy of Sciences of the U.S.S.R. in Moscow (founded by Peter I the Great in 1724), which combines the functions of a society of learned men (*cf.* Great Britain's Royal Society) with those of a large research organization. It is responsible for about 100 research institutes. It has throughout its career had practical tasks assigned to it; but for most of the time it has tended to concentrate on fundamental scientific investigation. This Academy is also the Academy of the Russian Soviet Federated Socialist Republic, in various parts of which regional branches have been established. The most important of these is in the new scientific town near Novosibirsk. Each of the other 14 republics of the U.S.S.R. has an academy of sciences, the largest and oldest being that of the Ukrainian S.S.R. (founded in 1918 and reorganized in 1919).

Industry and industrial research, including thousands of institutes, laboratories, and bureaus (some of them very small), are administered by the State Planning Commission (Gosplan, founded 1921), by more than 40 regional economic councils (*sovnarkhozi*), and by about 60 state committees some of which have all-union responsibility. The committees are in effect special ministries which secure liaison between industry and the central government and provide the technological foundation for the work of Gosplan. Some of them are responsible for progress in whole industries, such as heavy power generation, transport engineering, instrumentation, automation and control, fuel, chemicals, and food, while others, called production committees, supervise not only research and development but also individual factories and enterprises. All of these bodies are responsible to the Supreme Economic Council of the U.S.S.R. In addition to the research institutes there are thousands of research laboratories and design and planning institutes and construction bureaus. Some are large and have international renown (*e.g.*, the I. V. Kurchatov Institute of Nuclear Physics in Moscow, or the Paton Institute of Welding in Kiev); and some occupy little more than one or two rooms.

Finally, research is carried out in the universities, but this is on a relatively small scale compared with that in the remainder of the country. In the past the view has been taken that universities exist to teach, research institutes exist to do research, and industry exists to design and produce. These rather clear-cut definitions have led to some difficulty of communication. There is growing insistence on the importance of strengthening the research potential of the universities, but this is proving difficult to bring about, and there is steady pressure from both scientists and government officials to end the rigid demarcation between teaching and research activities.

Research Coordination.—The Marxist view is held to lead to the concept of science as an organism with mutually dependent parts which serves the economic needs of the country. The question is: Who is to provide the brain of the organism—or, in the words of Academician A. N. Nesmeyanov, a former president of the All-Union Academy of Sciences: "Who is to conduct the Soviet Scientific Orchestra?" The indications, about 1959, were that the All-Union Academy would undertake the task; at about that time the Academy listed the "Thirty Basic Directions of Science," resolving to concentrate its forces on these (23 of them being within the field of physical science and the remainder being concerned with history, linguistics, law, etc.). The "basic directions" concentrated attention on fairly broadly defined fields which were considered to have high economic significance; *e.g.*, the problem of controllable thermonuclear synthesis and the nature of elementary particles, in atomic physics; geophysical research; and photosynthesis, nutrition, and development of plants.

But in 1961 another state organization, the State Committee for the Co-ordination of Scientific Research, was formed and given executive powers, control over the finance of research and development, and a broad mandate to eliminate "parallelism" or duplication of effort throughout the Soviet Union.

The following years saw intense reorganization. The All-Union Academy of Sciences shed almost one-half of its institutes, mainly those of the Technical Sciences Division, engaged on engineering problems. These were transferred to the state committees and to industry. State coordination committees were founded in all of the republics.

By the mid-1960s a division of responsibilities for coordinating research appeared to have been established between the All-Union Academy of Sciences and the All-Union State Co-ordination Committee. Broadly speaking, the academy was to be concerned with the more fundamental scientific work and was to coordinate the research programs of all the republican academies of sciences in addition to its own; the committee was to concentrate more on applied research or development. Scientific councils were set up to guide development along most or all of the "basic directions" of science, their members being drawn from the academies, the government, the universities, and industry. "Leading institutes" were appointed to lead the attack in each direction.

Important weapons in the elimination of "parallelism" and the improvement of efficiency are the information services and technical libraries. The chief scientific information centre (and the largest in the world) is the All-Union Institute of Scientific and Technical Information, VINITI. With a permanent staff of 2,500 and more than 22,000 specialists working part-time, it produces 750,000 abstracts of Russian and foreign scientific and technical papers each year.

Finance and Staffing.—The "science budget," according to Soviet sources, was approaching 5,000,000,000 roubles, or £2,000,000,000 per annum at the 1964 rate of exchange. This figure is not very meaningful, however, since productivity, the concentration of resources on specific targets, and standards of living, all have to be taken into account in assessing its real value.

The U.S.S.R. has about 400,000 "scientific workers," roughly half of whom work in research institutes and half in higher educational establishments; but the difficulties of definition preclude any precise estimate of the scientific endeavour of the country in terms of manpower. At all events it is gigantic; and planning on such a scale, especially according to the rigid Soviet specifications, presents enormous problems.

(A. G. Fo.; Ed. G. H.; X.)

RESEDACEAE, the mignonette family of dicotyledonous annual and perennial herbs and shrubs. There are six genera and about 70 species.

Reseda odorata is the fragrant mignonette (*q.v.*), a popular garden annual; *R. luteola* is dyer's rocket or weld.

RESENDE, ANDRÉ DE (*c.* 1499–1573), the father of archaeology in Portugal, became a Dominican friar but, about 1540, entered the ranks of the secular clergy and was made a canon of Évora. He traveled in Spain, France, and Belgium and corresponded with Erasmus and other leading humanists. He was also intimate with King John III of Portugal.

Resende died in Évora, Sept. 9, 1573.

Resende's main Portuguese works are *História da antiguidade da cidade de Évora* (1553) and *Vida do Infante D. Duarte* (1789). His chief Latin work is *De antiquitatibus Lusitaniae* (1593).

See Francisco Leitão Ferreira, *Notícias da Vida de André de Resende,* ed. by A. Braamcamp Freire (1916).

RESENDE, GARCIA DE (*c.* 1470–1536), Portuguese poet, chronicler, and editor, whose life centred around the Portuguese court during the period of splendour and achievement under John II, Manuel I, and John III. Born at Évora, he began to serve John II as a page at the age of ten, becoming his private secretary in 1491. He continued to enjoy royal favour under King Manuel and later under John III. In 1498 he accompanied Manuel to Castile; and in 1514 went to Rome with the admiral Tristão da Cunha, as secretary and treasurer of the famous embassy sent by the king of Portugal to offer the tribute of the East at the feet of Pope Leo X. He died at Évora on Feb. 3, 1536.

Resende's *Crónica de D. João II* (1545), though largely plagiarized from a work by Rui de Pina (*c.* 1440–*c.* 1523), contains personal anecdotes which give it special interest. Much of his work provides an invaluable insight into the social life and manners of the period. In the 300 stanzas of his *Miscelânea* he surveys with wonder and pride, and not without social criticism, some of the notable events (including the great Portuguese discoveries) of the age in which he lived. The *Cancioneiro Geral* (1516), a vast anthology edited by Resende, and containing compositions of his own, is the chief source of knowledge of late medieval Portuguese verse.

Bibliography.—*Livro das obras de Garcia de Resende* (1545; 2nd ed., containing the *Miscelânea,* 1554); *Cancioneiro Geral,* ed. by A. J. Gonçalves Guimarães, 5 vol. (1910–17); *Crónica,* ed. by G. Pereira (1902); *Miscelânea,* ed. by J. Mendes dos Remédios (1917).

(T. P. W.)

RESERVOIR. Water storage reservoirs are places where water, accumulated from the flow of streams and rivers, is retained to serve the needs of man.

Changes in weather cause the natural flow of streams and rivers to vary greatly throughout the year and from year to year. There are periods of excess flows and valley flooding following heavy rains or during the melting season of snow-fed streams, and low flows (in some cases no flow at all) in periods of dry weather and droughts. The role of water storage reservoirs generally, therefore, is to impound water in periods of higher flows so that it may be released gradually during periods of lower flows.

Simple storage reservoirs were probably created early in man's history to provide drinking water for human beings and domestic animals and water for agricultural irrigation in areas where streams intermittently ran dry. The advance of civilization and the growth of population have been accompanied by an increasing use of water, creating a need for more extensive water storage facilities. From southern Asia and northern Africa the construction of reservoirs spread to Europe and the other continents. In the 20th century water storage reservoirs in ever increasing numbers are essential to control floods and provide assured supplies of water in large quantities for a multitude of vital uses. (*See* Hydraulics, Applied.)

On-Channel and Off-Channel Storage.—Reservoirs ordinarily are formed by the construction across river or stream valleys of dams, which vary from relatively simple earthen embankments to complex masonry structures (*see* Dam). In special situations off-channel reservoirs may be provided, making use of diversion structures and canals or pipelines to convey water from the stream or river to natural depressions or artificially created storage basins situated outside the river valley from which the water supply originates. Off-channel storage is also common in pumped storage hydroelectric power schemes; in these, during periods of low demands for electricity, the surplus electricity is used to pump water to reservoirs at a higher elevation, the stored water being released to generate electricity during periods of peak demands.

Gated and Ungated Outflow Control.—A feature common to all storage reservoirs is some form of outlet by which the rate of outflow of water may be regulated. The outlet may be pipes through the dam, tunnels through the dam abutments (valley walls), notches through the top of the dam, or canals or pipelines leading from a point along the perimeter of the reservoir. In many cases valves, or movable gates, which can be opened or closed as the need arises, are provided in the outlet passageways. Reservoirs with such controlled outlets can retain water for long periods and thus are frequently referred to as retention reservoirs. Reservoirs for practically all purposes except flood control are of this type, and most of the larger flood control reservoirs also have such controlled outlets. (*See* Dam: *Outlets from Reservoirs.*)

"Retarding" reservoirs, used to retard temporarily the discharge of water during floods, do not have valves or gates in the water outlet passageways; instead, the outlet pipes or notches are built to a size that will permit only a limited rate of flow to be discharged. Ordinarily these ungated outlet passageways are designed so that the rate of water discharge up to full reservoir level approximately equals the safe carrying capacity of the stream channel downstream from the dam. As a flood flows into such a retarding reservoir, the release of water into the stream below is automatically restricted to nondamaging rates without the necessity for any change of valve or gate openings as the flood progresses.

This feature is particularly desirable in small watershed-type flood control structures where floods may occur at any time of day or night and last only a few hours. Thus, almost all small flood control reservoirs controlling runoff from a drainage area of only a few square miles are of the uncontrolled outlet, retardation type. In some special situations, of which the Miami River Basin (Ohio) is a noteworthy case, considerably larger flood control reservoirs have been constructed with uncontrolled discharge outlets. But in most cases of large flood control reservoirs on large streams, more effective flood protection can be provided for greater distances downstream by use of controlled outlets, allowing reservoir discharges to be varied to suit the differing conditions of flood situations as they arise. In these cases, of course, floods last much longer, and there is time for river-control engineers to collect and analyze information on each flood as it progresses and to vary the rates of water discharge from each reservoir for most effective control. (*See* River.)

Sedimentation.—The flowing water in natural streams and rivers transports varying quantities of sedimentary materials, depending on the nature of the watershed and the physical characteristics of the watercourse. The reduction in flow velocity that results when the stream flow is impounded in a reservoir greatly reduces the sediment transport capacity, so that much sediment is deposited in the reservoir. On a stream carrying heavy loads of sediment this silting up of the storage area may severely shorten the useful life of a small reservoir. Even in larger reservoirs on larger rivers, sedimentation can be a serious problem. Removal of the deposited sediments from reservoirs is generally too costly to be practical. The usual procedure in planning a reservoir on a sediment-laden stream, therefore, is to provide a reserve of stor-

age capacity to offset the storage depletion caused by sedimentation.

Water Losses from Reservoirs.—Water may be lost nonproductively from storage reservoirs by evaporation from the surface, by seepage into the surrounding soil or rocks, and by seepage through the dam foundations. Seepage losses ordinarily can be reduced to negligible proportions through adequate geological investigation and treatment at the time of project design and construction. Evaporation losses, however, often are of major consequence. Gross evaporation from water surfaces in the temperate and tropical climatic zones may amount to several feet a year. In humid regions this is offset by precipitation accretions directly to the water surface of reservoirs, so that the net surface water loss may be moderate or negligible. But in regions of lower rainfall the net water loss by evaporation may be substantial, amounting to five feet or more of water annually in some desert areas. In Australia, the world's driest region, evaporation exceeds rainfall over about three-quarters of the continent and is at least double the rainfall over half the country. At Broken Hill, where the average annual rainfall is about 7 in. (178 mm.), average potential evaporation loss is about 96 in. (2,438 mm.). From reservoirs in South West Africa, annual evaporation losses range from about 80 to 100 in. (2,032–2,540 mm.). In East Africa losses generally run from 48 to 96 in. (1,219–2,438 mm.) of water and may be as high as 120 in. (3,048 mm.). The highest mean annual evaporation figures recorded include those for Bulawayo, Rhodesia, 111 in. (2,819 mm.); Yuma, Ariz., 100 in. (2,540 mm.); and Hyderabad, India, 148 in. (3,759 mm.).

Evaporation losses thus can become critically important in water planning in dry regions when attempts are made to fully utilize the available natural water supply. In extreme cases, evaporation from the additional water area created by reservoirs can offset the gain in firm water supply that otherwise would be provided by the additional amount of water stored. Similarly, indiscriminate construction of great numbers of small, shallow reservoirs in a watershed may seriously deplete the total water yield of the parent stream.

Considerable success has been achieved in experimental programs for reducing evaporation losses, notably in Australia, Africa, and the U.S., by the application of a liquid, monomolecular layer of a saturated long-chain fatty alcohol such as hexadecanol on the water surface. Substantial reductions in evaporation losses from reservoirs are in prospect as practical suppression methods are developed for widespread use. In ordinary circumstances, however, evaporation losses are not critical and can be accommodated by moderate increases in storage capacities or by tolerating moderate decreases in firm water yields.

Single- and Multiple-Purpose Reservoirs.—Early development of rivers was accomplished principally by use of so-called single-purpose reservoirs, usually as isolated units; and many, especially the smaller, reservoirs are still constructed as single-purpose developments. However, aided by governmental programs for comprehensive development of river basin areas, the prevailing trend in the 20th century has been toward construction of multiple-purpose reservoirs, particularly on the larger streams and rivers.

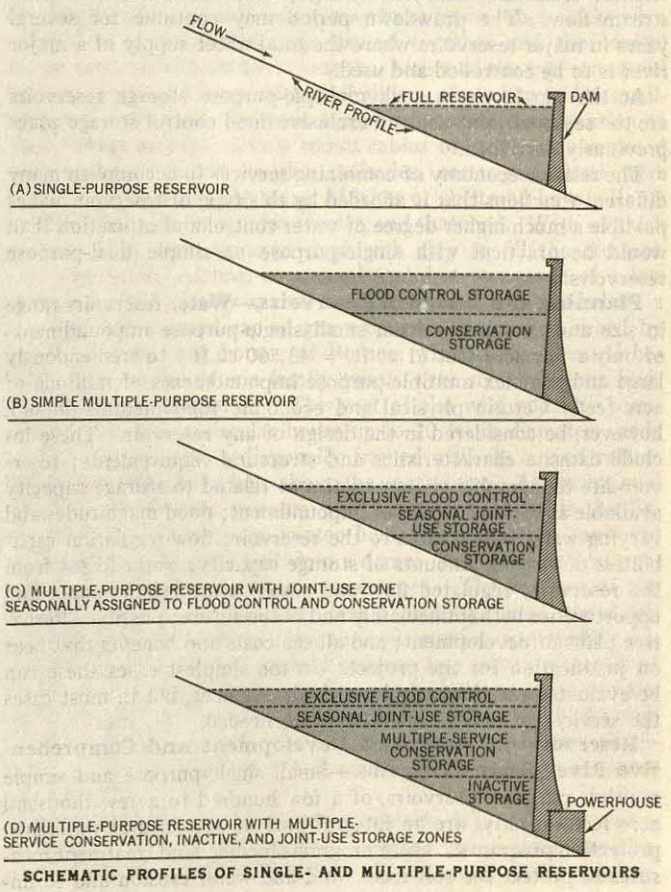
Single-Purpose.—A single-purpose reservoir, illustrated schematically in (A) of the figure, is designed to fulfill a single function, even though other benefits may accrue. Thus, a reservoir constructed simply to supply water for irrigation is considered as a single-purpose (irrigation) reservoir, even though it might have some incidental value for other purposes. Other functions of a single-purpose reservoir may be power generation, navigation, flood control, municipal and industrial water supply, low-flow regulation, recreation, etc.

The manner in which water is stored in or withdrawn from single-purpose reservoirs varies considerably, depending on the function. Thus a flood control reservoir is normally empty except at time of flood, when sufficient excess water is impounded to prevent over-bank flooding downstream; the impounded water is released as rapidly as practicable after each flood so that full storage space will be available when the next flood occurs. In contrast, single-purpose irrigation, navigation, and water supply reservoirs are normally kept filled, except when stored water must be drawn off to supplement deficient natural stream flows; the storage space is refilled as soon as practicable after stream flows again increase.

A variant of the latter type of operation is used for a single-purpose power reservoir where a power plant is served directly from the reservoir. The rate at which power can be generated is a function of (1) the amount of head (*i.e.*, the difference in elevation) between the level of the water in the reservoir and the level of the water downstream from the power plant and (2) the rate of water-flow through the power plant. Thus a single-purpose power reservoir is normally kept full except when deficient natural stream flows must be supplemented with stored water in order to supply the increased rate of flow necessary to generate power, but the amount of storage drawdown (*i.e.*, the decrease in storage level) in low-flow periods is restricted to a lower limit sufficient to provide the minimum head needed to operate the power turbines.

Multiple-Purpose.—Multiple-purpose (sometimes called multipurpose) storage reservoirs, designed to serve two or more principal functions, usually contain two or more zones, or layers, of storage, impounded behind a single dam. Where two (or more) functions need to be served, it is less expensive to build and maintain a high dam and a large reservoir than it is to build and maintain two smaller dams and reservoirs.

In simple cases, as illustrated schematically in (B) of the figure, a multiple-purpose reservoir may consist of two zones, or layers, of storage, each adequate to serve its own function and operated more or less independently of the other. For example, the lower zone might be provided for water supply and kept full except as drawdown is necessary to supply water in low-flow periods; and the upper zone might be provided for flood control and kept empty except during and immediately after floods. This would be termed a multiple-purpose flood control and water supply reservoir. Similar combinations of storage for flood control with storage for irrigation, navigation, or other water conservation functions are possible. Multiple-purpose designs of this type were the first generally used in the transition from single-purpose reservoirs.



SCHEMATIC PROFILES OF SINGLE- AND MULTIPLE-PURPOSE RESERVOIRS

A seasonal joint-use storage zone, interposed between the flood control storage zone and the conservation storage zone, as illustrated schematically in (C) of the figure, can be used effectively in regions where major floods are limited to well-defined seasons or where there are consistent high-water and low-water periods at different times during the year. In many areas of the world the annual stream runoff has pronounced patterns of this sort; it is particularly evident in streams fed by the seasonal melting of high-altitude mountain snow or in regions where precipitation varies substantially from season to season, as in monsoon areas. In these situations the storage capacity in the joint-use zone is assigned to flood control and emptied of water by the beginning of the main flood season; this zone is then refilled as the flood season draws to a close and is assigned to conservation usage until the onset of the next flood season. The relative volumes of storage that can be assigned effectively in the seasonal joint-use storage zone and are needed in the exclusive flood control and conservation zones depend upon the seasonal characteristics of runoff in any given stream. In the Columbia River Basin in the northwestern U.S., for example, the flood season is so well defined that all flood control storage requirements can be served adequately by the seasonally assigned joint-use storage capacity, and no year-round exclusive flood control storage capacity is required. This is a rather exceptional situation, however.

The maximum application of the multiple-purpose, joint-use reservoir storage concept is illustrated by (D) of the figure. Lowermost in a reservoir of this type is an inactive storage zone used to provide an assured minimum water level for any of several purposes, such as power head, water diversion from the reservoir, or navigation and recreation on the lake. After its initial filling, this bottom zone ordinarily remains permanently filled.

Above the bottom storage zone is a multiple-service conservation zone that serves to augment low natural stream flows for several different uses, such as navigation, irrigation, and power generation, as well as other functions. This conservation storage zone is filled in times of above-normal natural stream flow and is drawn down as necessary to sustain the desired level of water releases from the reservoir during periods of deficient natural stream flow. The drawdown period may continue for several years in major reservoirs where the total water supply of a major river is to be controlled and used.

At the top levels in such multiple-purpose storage reservoirs are the seasonal joint-use and exclusive flood control storage zones previously described.

The relative economy of combining services to accomplish many different functions that is afforded by this type of reservoir makes possible a much higher degree of water control and utilization than would be practical with single-purpose or simple dual-purpose reservoirs.

Planning and Design of Reservoirs.—Water reservoirs range in size and complexity from small single-purpose impoundments of only a few acre-feet (1 ac-ft. = 43,560 cu.ft.) to tremendously large and complex multiple-purpose impoundments of millions of acre-feet. Certain physical and economic fundamentals should, however, be considered in the design of any reservoir. These include damsite characteristics and structural requirements; reservoir-site topographic characteristics as related to storage capacity available at various depths of impoundment; flood magnitudes and varying water inflow rates to the reservoir; flow-regulation capabilities of varying amounts of storage capacity; water losses from the reservoir; regulated flow and water usage requirements and opportunities both immediately and in the future; possible alternative plans of development; and all the costs and benefits that bear on justification for the project. In the simplest cases these can be evaluated satisfactorily by a single engineer, but in most cases the services of several specialists are needed.

Reservoirs in Watershed Development and Comprehensive River Basin Programs.—Small single-purpose and simple multiple-purpose reservoirs, of a few hundred to a few thousand acre-feet capacity, are an integral part of agricultural watershed protection programs. These programs include land treatment measures to protect the soil from wind and water erosion and to improve productivity. They also include companion structural programs for water flow control, including small reservoirs specifically designed as components of individual watershed work programs. The reservoirs impound excess flows during periods of high runoff, to reduce flood damage along the small watercourses and streams in the watershed, and in many cases they provide rural water supplies and local recreation facilities.

Reservoirs of all sizes and types play vital roles in comprehensive river basin plans for control and utilization of a major basin's water resources. Under the basin planning concept, the collective effects of many reservoirs acting as a coordinated system, as well as the effects of individual reservoirs, are considered in locating and determining the size of the reservoirs and associated works. In most basin plans, single-purpose and simple multiple-purpose reservoirs are located on subtributaries and tributaries of the principal basin river. Their functions may include flood control, water impoundment and low-flow regulation, and power generation. In some basins, conditions also permit the location of large multiple-purpose reservoirs on the main river. In addition to reservoirs, basin plans include associated works, such as flood control levees and flood walls, navigation channels, pumping plants, irrigation canals or water supply pipelines, power plants and transmission lines, and other features. All of these are planned as integral or compatible elements of one overall basin program.

An outstanding example of the use of reservoirs in a comprehensive basin plan exists in the Missouri River Basin in west north-central U.S. The Missouri Basin program includes six major multiple-purpose reservoirs constructed by the U.S. Army Corps of Engineers on the main stem of the Missouri River and more than 100 major tributary reservoirs in programs of the Corps of Engineers and the U.S. Bureau of Reclamation; the total storage capacity of the reservoirs in the basin exceeds 100,000,000 ac-ft. This program provides flood control, irrigation, navigation, hydroelectric power generation, sediment retention, recreation, and other needs. A high degree of coordination is required to operate such a major program. In the Missouri River Basin this has been provided by special interagency reservoir operations coordinating committees and a special Missouri River reservoir control centre.

All the major reservoirs of the world are similarly multiple-purpose, and all, because of the immense size of the projects, have been constructed by or for government agencies. In the U.S. Lake Mead, the reservoir formed by Hoover Dam on the Colorado River, provides a total storage capacity of 31,047,000 ac-ft. (38,296,474,000 cu.m.) for irrigation, flood and silt control, domestic and industrial water supply, and power generation. Glen Canyon Reservoir, part of the upper Colorado River Basin project, has a capacity of 28,040,000 ac-ft. (34,587,340,000 cu.m.), while Oahe Reservoir in South Dakota—a power, navigation, irrigation, and flood control project—has a capacity of 23,600,000 ac-ft. (29,110,600,000 cu.m.). The reservoir formed by Kariba Dam on the Zambezi River between Zambia and Rhodesia in Africa has a total capacity of 130,000,000 ac-ft. (160,368,000,000 cu.m.) for power generation and flood storage. In India, the Rihand Reservoir (8,600,000 ac-ft. [10,607,900,000 cu.m.]) on the Rihand River, the Bhakra Reservoir (8,000,000 ac-ft. [9,868,000,000 cu.m.]) on the Sutlej, and the Hirakud Reservoir (6,600,000 ac-ft. [8,141,100,000 cu.m.]) on the Mahanadi provide for power generation, irrigation, and flood and river control. Lake Eucumbene, formed by damming the River Eucumbene in New South Wales, Austr., is the key storage of the Snowy Mountains hydroelectric scheme, but its capacity of 3,600,000 ac-ft. (4,761,310,000 cu.m.) also provides water for irrigation. The reservoir behind the Volgograd Dam on the Volga River in the U.S.S.R. has a total capacity of 47,020,000 ac-ft. (58,000,000,000 cu.m.) for power generation and for flood and river control.

RESHAT NURI GUNTEKIN (1892–1956), Turkish novelist, short-story writer and playwright, first achieved fame with his *Chalikushu* (1922), the most popular Turkish novel of the day. Born in Istanbul, he was educated in Izmir and Istanbul and, after teaching in various schools, traveled widely in Anatolia as an inspector of education. He was elected to parliament (1939)

and later became Turkish delegate to UNESCO. In *Chalikushu* (Eng. trans., *The Autobiography of a Turkish Girl,* 1949) he combined a realistic description of the Anatolian scene with romance. Other novels and short stories in the same vein included *Aksham Guneshi* (1926; Eng. trans., *Afternoon Sun,* 1951). *Yeshil Gece* (1929), a penetrating study of the reactionary elements in Turkey, initiated the second phase of Guntekin's career, the writing of a series of novels dealing with the social problems brought about by radical changes in Turkish life. His style is easy and straightforward, though sometimes almost too sentimental. He died in London, Dec. 6, 1956. (F. I.)

RESHID PASHA, MUSTAFA (1800–1858), six times Ottoman grand vizier of Turkey, was born at Istanbul on March 13, 1800. The protégé first of his uncle Ali Pasha and then of Pertev Effendi, a famous poet and statesman, Reshid was successively, during 1829–39, private secretary of the grand vizier Selim Pasha, secretary of the divan, member of a commission sent to Egypt (1833), ambassador in Paris and London, and minister of foreign affairs. During his stay in the French and British capitals he studied Western civilization and won the friendship of the principal French and British statesmen. He supported the westernization reforms of the sultan Mahmud II and after the death of Mahmud was charged by Sultan Abdul-Mejid I with the preparation of a new program of reforms. Elaborated in the form of a rescript or decree (*khatt-i-sherif*), this program was proclaimed on Nov. 3, 1839, by Reshid, in the presence of the sultan, the ambassadors of the powers, and Ottoman dignitaries, at the royal court at Gul-Khane. This rescript became the Magna Carta of the subjects of the Ottoman Empire, guaranteeing them equality, without distinction of race or religion, and security of life and property. Although these provisions were not completely carried out, Reshid became the symbol of westernization reform (the *tanzimat*). Between 1839 and 1858 he was twice appointed minister of foreign affairs and six times grand vizier.

With the support of Lord Stratford de Redcliffe, the British ambassador, Reshid abolished the slave trade and introduced new codes of commercial and criminal law. He also introduced regulations to end the traffic in favours and appointments. A supporter of France and Britain in his foreign policy, Reshid was grand vizier at the outbreak of the Crimean War. He died on Dec. 17, 1858. *See* also TURKEY: *History.* (E. Z. K.)

RESIA, PASSO DI (Ger. RESCHEN SCHEIDECK), an Alpine pass 4,947 ft. (1,508 m.) high which separates the lower Engadine section of the Inn Valley in Austria from the Val Venosta, the upper Adige Valley in Italy, thus forming a watershed between the Adriatic and Black seas. The Austrian-Italian frontier is about 1 mi. N of the pass; the Italian hamlet and lake of Resia are below, at an altitude of 4,911 ft. (1,497 m.). Below Resia village is the old, abandoned refuge of San Valentino alla Muta (Sankt Valentin auf der Haid), mentioned as early as 1140. The Resia Pass road starts from Landeck in Austria, follows the Inn as far as Pfunds, then rises slowly to the Finstermünz Pass 3,100 ft. (945 m.) above the Inn gorge, and continues past the village of Nauders to the Resia Pass. The road then descends through the Italian towns of Malles and Glorenza to Merano and Bolzano, where it joins the Brenner Pass road and railway. (G. KH.)

RESIDENCE, in general, a place of abode. In law, it is an ambiguous term frequently found in statutes. Used in such a context, residence normally bears the same meaning as domicile. *See* DOMICILE AND RESIDENCE. (W. L. M. R.)

RESIDENTIAL ARCHITECTURE. This article deals with the evolution of structures for human habitation, particularly single-family units, from earliest times to the present, in all parts of the world. (A discussion of the factors involved in the design and construction of contemporary dwellings will be found in HOUSE DESIGN. For discussions of multifamily structures, *see* APARTMENT HOUSE and HOTELS AND INNS; for social context of residential architecture, *see* HOUSING; CITY PLANNING; and ZONING. *See* also ARCHITECTURE.) The dwelling is the oldest branch of building, dating from man's first crude solutions for his most pressing problems: protection from the elements, wild beasts and human enemies. The architecture of shelters has developed extensively since the late 19th century.

Separate dwellings developed in three principal types: in hot climates the rooms usually were open or they surrounded an open-air courtyard; in colder regions the rooms generally were placed together in a compact block to facilitate heating. The third type was informal: the rooms were strung in rows at will. Bricks appeared with the beginning of civilization in Mesopotamia. Wood was the staple residential building material; brick and stone were employed in more luxurious houses. Two distinct methods of construction developed: one used the solid load-bearing wall, originally of rock or adobe, and later of masonry or reinforced concrete; the other method employed a framework of wood or, later, metal, with a covering of reeds, bark, wooden boards or, eventually, various composite materials. After the middle of the 19th century more glass and metal were introduced into the structure and, in an uneven progress, mechanical and electrical labour-saving devices were added to the ordinary house. Technical improvement in housing (*e.g.,* safety, comfort, sanitation) was complicated, however, by social pressures and by various intellectual and artistic trends.

Public buildings and palaces, monuments on which a higher art of building design was concentrated, were emulated in private dwellings. Residential design followed the main stream of public architecture through historic periods and styles, but was always a little more inclined to place convenience before effect. In western society, from the time of the Renaissance, the house came to be thought of as a vehicle of self-expression, and attracted the attention of architects. During the 20th century, residential architecture often led other forms of design.

The evidence of housing in prehistoric and preclassical eras is scant, and to some extent historians' accounts are in conflict. Nevertheless the houses of each important era may be visualized from archaeological fragments and knowledge of the materials that were available to the builders.

Primitive.—Masonry construction may have begun when the cave dweller sought to elaborate his cave by partially closing the mouth with a wall of piled rocks, or by adding external baffle walls, as in prepueblo dwellings on river banks in parts of the U.S. southwest. Frame construction may have begun when sticks were planted in a circle, their tops bound together and the conical frame covered with thatch or leaves. Either of the two structural systems were used by prehistoric builders, according to the availability of materials. Defense was an important consideration to early village settlers. Little round cabins of stone, clay or wood were gathered within wooden palisades, rectangular huts were raised on piles above the water of lakes or sheltered bays. Roofs were pitched high on wooden frames, and thatched. Walls of thick wooden slabs were smeared over with clay to fill the crevices.

In the typical African compound each hut was made of a low circular wall of closely spaced and plastered sticks, roofed by a tall, conically framed cap of grass thatch. Huts were linked by fences. In the long houses of Borneo, which were elevated beside a river, series of one-family rooms were strung in long lines behind common verandas. The yurt of the wild nomadic Mongolian tribes was a circular house up to 20 ft. in diameter, made of felt fastened over a diagonally framed wall, its curved rafters rising to a wide smoke hole above the central fire. An exceptional example of primitive masonry and indigenous design is the Eskimo's igloo, a temporary winter home of compacted snow cut into beveled blocks and built into a dome. American natives produced several other ingenious house types. The wigwam of the Penobscot Indians of the north was a primitive cone, about ten feet wide and ten feet high, but the construction was slightly advanced. Bark paneling was held between two separate frames of wooden poles lashed together at the ends. The construction of the tipi of the nomadic Indians on the semiarid plains was similar, but decorated hides or canvas (in the 20th century) formed a paneling more flexible than bark, and made the whole structure more easily portable.

The long house of the Iroquois tribes in the northeast was a windowless, rectangular building occupied by several families, each with an open alcove of its own. It was made, as the wigwam,

of big bark panels held in a double framing. The pueblo of the U.S. southwest was a multistory agglomeration of family cells in adobe or stone. The ends of the closely spaced logs that supported the adobe slab roofs projected through the walls. Each floor receded from the one below, forming irregular roof terraces, from which ladders led up and down to other cells. (*See* also INDIAN, NORTH AMERICAN.)

Between the 17th and 19th centuries European colonists often revived the crudest types of mud and stick construction. Primitive dwellings are still being built in many parts of the world. In north Australia nomadic aborigines sleep in caves or behind low bark breakwinds erected for the night. Neolithic types of lake villages are still occupied in Cambodia and New Guinea. Various rude forms of wood hut and mud cabin persist in Africa and parts of Asia. (*See* DWELLINGS, PRIMITIVE.)

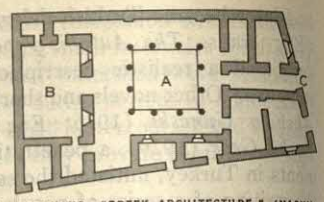
Egyptian.—The great advances of Egyptian civilization did not extend to the poorer family house. It was still no more than a sleeping room and a storehouse, a low single cell open on one side. It was made of mud brick or of reeds plastered with mud and was roofed with palm leaves. However, the government did provide protection, eliminating the necessity of stockades, and the equable weather encouraged an outdoor life. Wealthier citizens built rooms behind or on either side of the central cell. The flat roof was strengthened with poles or with barrel vaults of brick and was used for eating and sleeping. Houses of leading citizens were either the block or the courtyard type, detached and sizable. A courtyard house was about 40 to 50 ft. square within a high surrounding fence. Rooms might occupy two sides of the square; the remainder was a semiroofed garden court serving as the main living area. In populous areas houses were pressed together on opposite sides of narrow streets. Often an outside staircase led to the flat roof. To the Egyptian the real home was the tomb (*q.v.*); it was the eternal habitation and the house was merely a temporary shelter. Nonetheless, the homes of the rulers were comfortable. An aristocrat's country house had a number of rooms grouped around a private courtyard. The house was set within a luxuriant formal garden enclosed by stables, storerooms and linking walls. Palaces were big, and the Pharaoh's central apartments were colourfully decorated and lavishly furnished for comfort and elegance. (*See* EGYPTIAN ARCHITECTURE.)

Western Asiatic.—The pattern of housing changed little in the Mesopotamian and Aegean cultures. The poor-man's house was generally a single-cell hovel. The middle classes had multiroom blocks of various sizes. The upper classes enjoyed elaborate buildings, reasonably comfortable and sanitary, with courts, gardens, loggias and colonnades developed into spatial compositions. Architecture was called upon to provide a rich visual background for the indulgent life. In Babylonia, although a somewhat more even distribution of wealth improved the standard of housing, the techniques of building did not advance beyond those of the Egyptians. For about 2000 years these techniques remained fairly constant. The poor man's cell was of mud brick, laid in the form of a tall pointed dome. Plain-faced stucco houses lined the winding, crowded, muddy city streets.

The middle-class house was built of sun-baked bricks; it was a compact block with a flat roof, which, when shaded by a light awning, was the principal living space. A rich merchant's house typically consisted of two stories, with thick brick walls, a central court ringed by dark, narrow rectangular rooms, and a veranda with bright awnings in front. Most of the rooms were storerooms, but some were used for refuge when both roof and court became too hot. Then the walls were watered and their fine white plaster surfaces were cooled by evaporation. (*See* PRE-HELLENIC ARCHITECTURE.)



MARQUAND, "GREEK ARCHITECTURE," (MACMILLAN)

FIG. 2.—PLAN OF GREEK HOUSE, DELOS

(A) Court, (B) chief room or thalamus, (C) main entrance

Greek.—In the golden age of classic Greece the houses of ordinary peasants were still crude cabins. A colder climate than that experienced by previous civilizations necessitated some heating. Through the brief cold winter, farm beasts shared single unpartitioned brick rooms with their owners. Smoke from a central hearth on the earth floor rose to a hole in the reed roof. Although the refinement of the monumental architecture was unsurpassed, the houses of even the illustrious Greeks were modest. Temples, theatres and public meeting places were the centres of living for men. Wives were restricted and generally segregated in rooms behind or above the men's quarters. Family life hardly existed. The thalamus, or inner chamber, was the official centre of house life. For the middle classes, three- or four-story rental tenements crowded the tortuous, earthy streets of the cities.

After the Macedonian conquest, the houses of the wealthy began to reflect some of the architectural qualities of the public monuments. The remains of a big house of Hellenistic date at Palatitza in Macedonia indicate multiple courts, long wings and ranges of rooms linked by colonnades. House exteriors became almost as formal as those of temples, and interiors were splendid with murals, statues, pottery and textiles. (*See* GREEK ARCHITECTURE.)

Roman.—The Roman house of every size and degree of wealth was centred around the atrium (*q.v.*). The atrium derived from the single cell of the primitive hut, with its smoke hole in the centre. As the room enlarged, so did the smoke hole, and columns were erected to support its edge. By the time of the empire the atrium had become a semiopen court ventilating and lighting surrounding rooms. The richer houses developed a peristyle, or court with a garden, at the back; a second story was added and the atrium was made resplendent with ornament and statues. The appearance of the reception rooms always took precedence over comfort in the family areas.

The middle-class house had a smaller atrium, sometimes roofed over, with kitchen and dining room behind and bedrooms above. The farmhouse combined barns, oil and wine presses, storerooms and the dwelling in one building around a courtyard. Poorer free men in Rome and its more crowded colonies lived in bare rooms in tall, dark insulae, or apartment blocks, some seven stories high. Augustus limited their height, in one of the world's first building regulations, to 70 ft. There are indications that they too were planned to surround a court in which the staircase rose past balconies giving access to the upper floors. On the street front the ground floor was occupied by shops. The façade above was usually of brick, pierced by rows of simple windows, a style of apartment housing that persisted into modern Italy. Sometimes the upper stories projected dangerously.

Medieval.—Until the 13th century the serfs of Europe lived in unrelieved squalor; sod huts partially dug out of the earth, or hovels made of low stone walls surmounted by roughly thatched roofs were typical dwellings. The early Norman castles of England were heavily fortified, dark and dirty and not intrinsically more livable than the poor man's abode. In the 13th century the manor house (*q.v.*) developed a little rugged comfort. It was centred on the hall (*q.v.*), a survival from Saxon times, to which were added buttery, pantry, larder and subsidiary compartments at one end and the solar at the other. The hall was sometimes 60 ft. by 20 ft., stone paved, with a central fireplace, small high windows, and a low dais at one end on which the family and guests took their meals. The solar was the withdrawing room and bedroom, the private family room. Walls were thick, of brick or stone and an increasing amount of half-timber work (*q.v.*). Window glass was a luxury; openings had shutters, pointed to match the Gothic arches.

The new bourgeois or middle class of the middle ages lived in houses of two or three stories packed into the narrow streets of expanding towns. Typical three-story houses of the 12th century are found at Cluny, France. In such a house a central light court cuts the narrow plan in two, with only a gallery connecting the front to the rear rooms. The front room on the ground floor is a shop, the rear a kitchen. The floor above has living rooms in the front, sleeping rooms in the rear. An attic fills the high roof space. The "Musician's house" at Reims (*c.* 1240) has a façade typical of the simple charm of the time, made notable by statues of musicians set in niches. The "Jew's house" at Lincoln is an early English town house with richly carved window arches in the Norman Romanesque manner. With their sensible plans and rudimentary plumbing these medieval town houses of northern Europe were potentially comfortable, and they changed little in 500 years. In the north of Italy town life matured earlier. Tall, sophisticated city palaces enclosed arcaded courts. The security of Venice permitted a more extroverted plan, with wider openings to the canal at the front and to the garden at the back. Walls were ornate in coloured marble and were animated by balconies, loggias and long ranges of windows, embroidered with Gothic tracery.

In rural areas the peasant's lot gradually improved and the farm-building complex developed, with barns, sheds and dwelling contained within a fence. Stone was usual in southern Europe, and wood in the north.

House planning, in the modern sense, began with a concern for the privacy of certain members of the household and for the accommodation of certain functions of living in English manors and the European burghers' houses. Between the 14th and 17th centuries rooms were increased in number and were more clearly differentiated. In England the great hall grew asymmetrical wings as required by function. Until the 16th century, however, circulation was tortuous, through rooms and up and down many stairs. The French château (*q.v.*) at this period was a century ahead of the English manor. With its romantic, pointed roofs and round corner turrets, its symmetry and elegance reflected in a wide decorative moat, it made a graceful transition from the grimly fortified Gothic castle to the open, formal Renaissance mansion.

FIG. 5.—PLAN OF CHARNEY-BASSETT, BERKSHIRE, ENG., 1270

(A) Hall, (B) chapel (upper story), (C) solar (upper story)

The English manor's wings, growing from each end of the great hall, eventually linked to enclose a courtyard (*e.g.*, Compton Wynyates, Warwickshire, 1520). Late in the 16th century the wings opened into a U-shape, releasing the confined courtyard. At the same time the moat was abandoned (*e.g.*, Hatfield house, Hertfordshire, 1607–11). The great hall decreased in size and importance; the main passage, expanded to a wide glazed gallery, became the biggest and most pretentious room. It was graced with wood paneling, coloured window glass, black and white checker marble floor, restrained plaster ceiling and elaborate chimney pieces. The exterior, while often retaining the pointed arch and a free disposition of windows, was more composed and symmetrically balanced, gradually adopting the formalism of the Renaissance. (*See* ROMANESQUE ARCHITECTURE; GOTHIC ARCHITECTURE; CASTLE.)

Renaissance.—In Italy the architectural formality that persisted even through the middle ages grew easily into a full-blown classic revival. The master of residential architecture was Andrea Palladio (1508–80). In buildings such as the Villa Rotunda near Vicenza he adapted the temple form to domestic use without sacrificing classic symmetry, proportion, scale or ornament. The use of giant porticos resulted in precise geometric plans based on the circle and the square, which were developed into three dimensions in accordance with mathematical doctrines. The Renaissance was received enthusiastically by the French court and yielded houses of elegant conception and charming detail. The style came late to England, delayed by Henry VIII's break with Rome and the consequent anti-Italian prejudice. During the 16th century a classic quality entered via northern Europe, and the first English professional architect (John Shute) and the first architectural historian (Henry Wotton) appeared. But the English Renaissance proper began with Inigo Jones (1573–1652), self-trained artist and scholar and generally considered to be the first major English architect. He introduced the Palladian (from Andrea Palladio) style of pure form and the revived classic order (*q.v.*). The plan concept ruled the elevation and all was "masculine and unaffected," as Jones noted during his Italian travels. His monumental houses for the nobility usually consisted of a simple cubical block dominated by the pavilion, or classic loggia, with its single order of tall columns. (*See* RENAISSANCE ARCHITECTURE; TUDOR PERIOD; ELIZABETHAN STYLE; JACOBEAN STYLE.)

Baroque and Neoclassical.—England's most famous architect, Sir Christopher Wren, was mainly occupied with monumental work, but during his time the "Wrenish" style, a reserved baroque, eclipsed Palladianism. For two prosperous generations of country-house building the classic orders gave way to some originality. Still the house had a rectangular plan, rigid symmetry, a hipped roof and eave cornices broken by central pediments. Early in the 18th century the Palladian style returned, to be replaced about the middle of the century by the characteristically English neo-classical manner known as Georgian. This was an elegant, simplified, lightly ornamented style looking to Rome and Greece for inspiration, and relying for effect on harmonious proportions in the severe rectangles of the façades and the fine, regular glazing bars of the windows.

FIG. 6.—PLAN OF THE HOUSE OF JACQUES COEUR, BOURGES, FRANCE, 15TH CENTURY

(A) Main entrance, (B) court, (C) gallery, (D) secondary hall, (E) great hall, (F) kitchen, (G) bedroom

Robert Adam perfected a graceful personal style drawn from

Greek and Roman precedents, plain in form but delicate in ornament, which was accused by its more robust opponents of being effeminate and paper-thin. A rich London house by Adam at 20 St. James street, a typically medium-sized house of its day and class, had seven main living and entertaining rooms on its tall ground floor, and bedrooms above. Within the narrow rectangular confines of the structure Adam shaped the music room as an oval and the dressing room as a circle. At the rear was a garden court enclosed by the stables and coach house. Smaller town houses, foregoing individuality, combined to form long façades, as in the magnificent curve of Royal Crescent at Bath. The typical house was plain red brick with simple windows, a thin cornice and a neat stringcourse above the arched, fan-lighted doorway.

Early in the 19th century the firm Georgian style divided into the Romantic movement with its exotic Gothic and eastern conceits, and the Regency style, with its plain stucco walls, curved bays and spidery shadows of delicate iron balconies.

Colonial.—Through the 17th and 18th centuries European colonists carried their local house styles to the Americas, Asia and the antipodes, changing them no more than was necessary to adapt them to new materials and changed climatic conditions. After a temporary phase of primitive shelter Early American house types appeared. In the densely forested lands of the north, clearing was an essential first task and wood the obvious choice for building. The lapped horizontal weatherboard or clapboard, hardly known in England, was used generally. The rectangular, frame house with two low stories and a high gable roof was centred on a brick chimney stack. Later a lean-to addition at the rear produced a "salt box" profile. The Cape Cod style grew from an ingenuous functional plan of four rooms on each floor clustering around fireplaces in the stack; a small stairway rose between the stack and the central front door. In Virginia, which was warmer and richer, the plan was longer and thinner and there was a chimney at each end. Brick was more common. The stair hall cut through the centre of the house and opened to front and back.

As early as 1667 Palladian books and plan publications carried more sophisticated architectural ideas across the Atlantic. Architects arrived early in the 18th century; a John James was practising in Boston in the 1730s. Soon the American Georgian style appeared, closely following the English model. In the north the style was adapted to wood construction with slender columns or flat pilasters. The rooms were tall, the plan compact. Fine moldings dressed the eaves cornice, fanlights, stairways and shuttered window trim. In the colonies at New York and Pennsylvania, German and Dutch influences were strong; in Virginia and Maryland great plantation homesteads settled in spacious lawns on river estates. These big houses were generously conceived and graciously furnished. They were characterized by the hospitable, heroic scale of a two-story portico in a single classic order. As far south as Charleston the Virginian influence was felt, but there the houses turned crabwise for protection: a formal Georgian end faced the street and tiers of veranda faced the private side garden.

In Mexico the Spanish colonial houses had plastered and pastel-washed rubble walls under sun-baked tile roofs. Rooms were arranged around terraces, arcaded courts, and fountains playing in private patios. (*See* IBERO-AMERICAN ARCHITECTURE.)

The Georgian and Regency styles were adapted in various ways to Australia, New Zealand and the islands of British colonization in the late 18th and early 19th centuries. The typical Australian country house was single-storied with a low, hipped shingle roof. It was surrounded by a wide, slim-posted veranda onto which the tall windows of the main rooms opened. (*See* COLONIAL ARCHITECTURE.)

Victorian.—During the second half of the 18th century, the most cultivated phase of European residential architecture, a profound change occurred in the poor-man's house. In the middle of the century the artisan, weaver, miller or farmer lived in essentially the same conditions as the freeman worker of earliest civilization. His house was also his workshop, and his children's place of work. By the end of the century the Industrial Revolution had interrupted the slow evolution of this house, not by transforming its building techniques but by upsetting the function of the home and the nature of family life. Most members of poor families spent days in the factory and nights in mass housing not unlike that of imperial Rome. Four- or five-story walk-up tenements gathered around the factories. They were ill-lit, poorly ventilated and the only outdoor living area they provided was on the pavement of a narrow street. The construction was brick, unencumbered with ornament or plumbing. By the middle of the 19th century, slum areas were extensive in most big cities. Room areas diminished and ingenious plans were devised to save space (*e.g.*, the New York "railroad" apartments with rooms packed four deep, only the end ones seeing daylight). Meanwhile the city was dissolving at the edges. Rail transport permitted middle-class workers to live away from their places of employment. Suburbs usually developed around the rail centres and radiated like spokes from the city. The typical Victorian suburban mansion was as elaborate as the palaces of earlier eras, but reduced in scale for a single family with servants and guests. The newly prosperous, hospitable manufacturers and merchants had no patience with cultivated tradition. Georgian and Regency taste was called mawkish and simplicity was seen as a poverty of dress unbecoming in the home of a man of substance. Ambition and acquisitiveness complicated the desire for comfort, sometimes resulting in a clutter of ornamentation unique in the world's history. The multiplying members of the lower middle class moved to the suburbs to nominally detached houses on narrow strips of land. The less successful man was able to emulate the mansion's ostentation effectively, thanks to the machinery of mass-produced moldings, pressings,

printings and castings; any desired decorative effect could be reproduced cheaply. The ordinary man began to reap some of the benefits of industry. Built-in equipment and mechanical appliance, including the fitted English bathroom, were novelties in expensive homes early in the century and gradually became commonplace toward the end of the Victorian era. The great increase in personal possessions produced a storage problem that was solved by the built-in cupboard, closet and pantry. Cellar central heating was introduced in the U.S. in the 1830s and was fairly general in mid-century American homes, as were centrally supplied water and gas. Waterborne sewerage began in Hamburg in 1843 but was not adopted by many cities until late in the century. Electricity had been proved an effective source of power by 1900. Industrial techniques did not, however, extend to the construction of the house. The promise, popularly recognized in the Crystal Palace in 1851, of a new world of mass-produced metal and glass homes, did not materialize as expected. (It had not yet arrived, but was still imminently expected, a century later.) No part of a wall or ceiling was left undecorated. During construction, handicraft ornament supplemented machine-made ornament. Graining, imitating expensive wood or marble, was often painted on plaster or plain boards, a practice about which John Ruskin (1819–1900) commented: "There is no meaner occupation for the human mind." Ruskin and William Morris (1834–1896) were among the few Englishmen who protested against commercialised design and the decline of taste. They sought a return to simple, natural ornament and an appreciation of genuine handcraft. In the U.S. the sculptor Horatio Greenough (1805–1852) called for the elimination of all ornament. These pleas had little effect. Ruskin helped to inspire the Gothic Revival, and Morris' medieval decorations helped it grow. In residential architecture the Gothic Revival usually manifested itself in tall gables with intricate fretwork ornament and pointed-arch windows, later enriched by polychromatic brickwork and ornate lead lights. It was the principal rival to a coarsened neoclassical style in the "battle of the styles," but there were many other revivals. Eclectic architects and builders raked history for embellishments and added to their houses distorted fragments of Norman castles, French châteaux, Swiss chalets, etc. The nadir of taste was reached in England about mid-century, in the U.S. after the Civil War.

Two major, separate revolts began toward the end of the 19th century. One was the *art nouveau* (*q.v.*) movement initiated in Brussels, an attempt at a new nonhistorical style in which form and ornament were to be based on nature's shapes. This produced only a popular passing fashion of superficial sinuous lines on the trimmings of a house. The other revolt slowly developed toward a rational, styleless architecture shaped to the function of the shelter by the nature of the construction, devoid of ornament. These concepts were the basis of nearly all of international modern architecture as it gradually evolved during the next half-century in the work of temperamentally diverse architects in widely separated localities. (*See* also MODERN ARCHITECTURE; ARTS AND CRAFTS MOVEMENT.)

20th Century.—The roots of 20th-century residential architecture may be traced in Morris' aim to elevate domestic taste, in the quasi-rational theories of the Frenchman E. Viollet-le-Duc (1814–1879), and in C. F. A. Voysey's big English country houses of the '90s, with their boldly composed roofs and plain white walls. Some of the most important formative steps were taken by non-domestic architects: Louis Sullivan in Chicago, Otto Wagner in Austria, Peter Behrens and Walter Gropius in Germany, Auguste Perret in France, and others. But the crystallization of the movement and a great number of the most auspicious early designs were in the residential field. Many of the best-known architects of the century, including Frank Lloyd Wright, Mies van der Rohe and Le Corbusier, first established their personal styles in houses.

A house on the Geneva water front in 1904 by Adolf Loos, exemplifying his passionate distaste for ornament, introduced the functionalist house. California houses in the early 1900s by Bernard Maybeck and Greene & Greene developed a carpenter-rationale unknown in Europe. However, the U.S. prairie houses by Wright (1869–1959) were published in Germany and injected a new enthusiasm into the European movement.

Although Holland was slow at first to accept the new movement, the vociferous *de Stijl* group appeared there in 1917. It formalized the theories of functionalism; it probably was largely responsible for the development in Europe through the 1920s and '30s of the naked white-plastered modern house in easily comprehensible cubist shapes. Plain blocks were fashionable for the first and only time; after half a century of ornamental excesses they seemed artistically satisfying, even when not accompanied by any creative idea.

In a postwar atmosphere the Bauhaus (*q.v.*) school was founded in Germany in 1919 by Walter Gropius. With its all-embracing concept of the creative simultaneity of technology and all the arts of living, it had untold influence on the development of house design throughout the world.

In France the Swiss-born architect Le Corbusier (1887–1965) contributed influential writings to the journal *L'Esprit Nouveau*. In 1930 he built his most famous house, the Villa Savoye, at Poissy; a wide white box, whose hollowness was emphasized by its open decks and by its being elevated on poles. It was one of the most vigorous expressions at that time of the new interest in negative form; *i.e.*, the composition of spaces rather than the proportioning of masses.

In Russia shortly after the revolution constructivism was a style recommended for the huge housing blocks. It was an experimental branch of modern architecture following structural methods. It soon met official reaction, and after 1930 the Soviet government adopted severe neo-Renaissance façades for its bulky apartment buildings.

The Stockholm exhibition of 1930 introduced modern architecture to Scandinavia. Sweden accepted the principles more thoroughly and naturally than any other country, and for many years the simplicity, without self-consciousness, of its houses and household wares received world-wide attention. Central urban-planning control, exceptionally high and level living standards, and a tradition of first-rate craftsmanship aided the development. Generally, 12-story elevator apartments were built near the cities, and 3-story walk-up flats and single-family houses formed satellite groups. All units were well planned and equipped to give comfort, if not privacy, and care was given to the external architectural relationships and the preservation of the best qualities of the landscape. Notwithstanding a certain monotony which developed later, Sweden thus produced the most cultivated and fully pervasive national pattern of housing in history.

Germany under Hitler called for a nationalistic style and outlawed the new architecture. Many of its leading designers left for England and later the U.S., where eventually they were responsible, with American confreres, for a revolution of taste against historic revivals. After World War II Germany returned to its earlier rational architectural principles for the design of many enormous apartment blocks. Its comparatively few single-family houses, however, tended to be designed in the traditional pattern of German country houses.

While the European functionalist phase developed through the early part of the century, most English-speaking countries persevered with architectural eclecticism. It was more restrained than in the 19th century and extremes, such as the Gothic Revival, were rare. But exotic effects continued to dress the faces of houses, such as, Italianate villa, Spanish mission and English style (outside England). At the same time more and more people wanted private, detached houses. In the 1930s some were "modernistic"; *i.e.*, ornamented with parallel grooves or streamlined curves or skyscraper profiles on the chimney tops.

During this time Frank Lloyd Wright built numerous houses of remarkable individuality, his artistic range including the wide, reposeful roofs of the Robie house, Chicago (1909), as well as the striking suspension of "Fallingwater" (1936–38) over a mountain stream in Pennsylvania. His favourite materials were wood and stone, his line horizontal, his spaces wide and subtly interrelated. He made each house an artistic idealization of free family life. In his retention of ornament and his increasing romanticism he steadily drew away from the Europeans. Not until after World

War II was his art popularly recognized in the U.S.; then it had at least superficial influence on many houses.

During this period it was often possible for the poor to possess the ancient symbol of independence, the private house. The cities' suburbs, which had been growing slowly for a century, escaped urban control. Young married people sought immediately to own a home, and the home was the centre of nearly all social contacts and entertainment. A new nomadic segment of the U.S. population rebelled and took to living in car trailers which compressed all the mechanical aids of the 20th century into the area of an Inca hut. Town housing remained comparatively stable in the U.S. The more prosperous cities proceeded slowly with slum-clearance schemes for their crowded tenement areas, usually rehousing the same number of people in taller blocks set apart on lawns. In many European and Latin-American countries, on the contrary, big new apartment blocks continued to increase the density of urban populations.

Most suburban houses were built without architects' guidance. Standard designs were repeated tirelessly with minor fashion changes and some colouring by local idioms. Mechanical equipment constantly increased and improved. Buckminster Fuller in 1927 designed a fully industrialized house hung on a central mechanized mast, and later many other proposals were made in the same vein. But society resisted radical change from the traditions of wood and brick.

Architectural character continued to be dominated by a few creative men whose well-publicized ideas carried to suburbs everywhere. Some were bent on perfecting anonymous, universal shelters in which each owner could create an environment to his taste. Most residential architects, however, still aimed to compose in spaces and textures a delightful background for the kind of life the occupants liked to lead.

Asiatic.—Before contact with the west and modern technology, antique rules of building in Asia descended unchanged from one generation of builders to another.

Indian.—Building rules were recorded in Sanskrit about A.D. 500 in a code determining sizes, proportions, structure and details of design down to the doors, windows and drains. The poor peasant of the plains had a single hut. The villager had a house of four huts—one each for the men, women and cattle, and one for cooking and storage—on four sides of a courtyard. The Hindu multifamily group repeated the court and its rooms for each brother. A rich-man's house extended the system again with extra stories.

In the thickly populated areas around great rivers the floors and walls were made of clay, the roofs thatched. In the arid northwest the walls were brick or stone, the flat roofs were of an

indigenous cement. In the western Himalayas the court was omitted, the stone walls rose two floors under a slate roof. In some parts intricate carvings adorned the balconies and surrounded the door and window openings.

The English in India developed a single-story house with a shaded veranda and well-ventilated rooms. It was known in the vernacular as a bungalow, a name which later came to mean in other countries a single-story house of any design.

Chinese.—The traditional Chinese house was a single-story row of rooms linked by a narrow veranda and surrounded by a high wall. A screen directly inside the entrance gate balked devils, who cannot negotiate corners. Brick was common, and adobe faced with brick made the thicker walls. The top halves of some interior partitions were open latticework with paper panels. Windows usually had decorated paper panes. The roofs had a characteristic drooping gable, suggestive of tent origins. Houses of the rich had black ebony carvings against their brick walls and beneath their green glazed tile roofs. The plain interiors were often well decorated with fine sandalwood or teak furniture and elaborate embroideries and porcelain. (*See* CHINESE ARCHITECTURE.)

Japanese.—In Japan the traditional vernacular house was based on an order of design that western civilization first approached in the 20th century. The house was light, adjustable, unpretentious, virtually unadorned and planned on a precise mathematical concept. The standard grass floor mat, about 6 ft. by 3 ft., was the module for all planning. Whether square or oblong each room was a multiple of the mat size (*e.g.*, a four-mat room). Posts on the perimeter of the veranda and at the corners of rooms supported the hipped or gabled roof frame. The roof was tiled or thatched on top and lined on its flat underside with boards or panels of wood. Some external walls, such as those for the kitchen and privies, were permanent in bamboo, boards or plaster. But the unique feature in the traditional Japanese house is that most exterior walls and nearly all interior partitions were movable screens sliding in grooves which ran in the floor and the ceiling between structural posts. These screens permitted the rooms to open to the veranda and to each other as required, and allowed for supervision of family activities by the patriarch.

The modern Japanese adoption of U.S. fashions threatened to end the tradition, but some Japanese architects have succeeded in advancing the structural principles of the unpainted wood and paper idiom without destroying its order, flexibility or unaffected artistry. *See* JAPANESE ARCHITECTURE.

(Ro. B.)

RESINS are among the most versatile of all chemical compounds, and their industrial applications are still expanding. Natural resins range from pitch and asafetida to frankincense, myrrh, and the fossilized form known as amber. Synthetic resins are the bases of products as varied as nylon, billiard balls, and equipment for softening or desalting water.

Prior to the introduction of synthetic resins, the term resin was applied exclusively to certain sticky substances in the form of yellow or brown deposits that exude from certain trees, particularly from the pine and the fir. As knowledge grew about the nature of such natural resinous products and the means by which similar compositions could be made by known chemical reactions, a large and ever-increasing number of products have been included in the category of resins. At first these laboratory

products were hesitatingly referred to as resinlike products, then as artificial resins and resin substitutes, and finally as synthetic resins. In almost every respect the natural resin can be replaced by one of the synthetic varieties in many industrial applications, especially in the molding and coating industries. By studying chemical reactions that lead to resinification, a better insight was gained concerning the chemical transformation that takes place in the natural product, and in certain instances it became possible to combine chemically the natural and the synthetic product to form a new material possessing unique properties.

At one time resins were recognized by certain well-known attributes, that is, by their transparency and amorphousness and by their brittleness and conchoidal fracture. Some synthetic resins fail to exhibit any of these characteristics; some are tough and colourless, others opaque and crystalline. There appears to be only one property common to natural and synthetic resinous products—in one stage of their existence both products are plastic.

The distinction between resins and plastics is at best arbitrary, since many of the later synthetic materials can be called both resins and plastics. Historically, it appears that the term resin was applied to those products primarily used as substitutes for the natural product in coating compositions, whereas the term plastic was used to designate those compositions that involved a molding operation in their fabrication. It is generally recognized that resins, plastics, rubbers, and fibres are part of one large group of chemical compounds, and by suitable transformations it is possible to change any one member of this group into another. (*See* PLASTICS.)

I. NATURAL RESINS

1. Resin Formation.—Resin formation in a tree occurs as a result of injury to the bark caused by wind, fire, lightning, or other means. Initially this secretion is fluid in nature and appears in the form of an oleoresin or as a balsam. In contact with air certain of the more volatile components evaporate, and the residue oxidizes, polymerizes, and gradually converts to a soft resinous product that is readily soluble in appropriate media. As the natural resin ages, it becomes more insoluble. When the resin flow from the tree is copious, some of the secretion passes into the ground, with the result that many fossil resins are found as buried deposits. Even in the case of the recent fossil resins, the chemical reaction leading to resinification may have proceeded for thousands of years. For example, the kauri pines are known to attain an average age of 1,000 years, and since resin can now be found in areas where the original forest has wholly disappeared, it is obvious that the resin must be extremely old, even though it is still soluble. The fossil resin, amber, is less soluble; its very existence indicates that the process and time of polymerization from the oleoresin to resin, to recent fossil resin, to fossil resin must be reckoned in geological periods.

2. Occurrence.—Resinous deposits are found in many parts of the world, and many varieties derive their names from the locality where they are collected. Certain tree emanations were utilized by the Chinese and the Japanese in their preparation of Oriental lacquers. There is reason to believe that the Incas and the Egyptians used varnishlike materials. The Carthaginians, Phoenicians, and Greeks were acquainted with resinous products, and the association between resins and varnishes can be seen in the derivation of the word varnish. This term appears to originate from Berenice, queen of Cyrene, the name the Greeks applied to amber. The term Berenice became corrupted gradually to Pheronice and then Verenice and Vernis.

3. Characteristics.—Any mucilaginous exudation of a tree is considered a gum. Shellac is a distinctive product inasmuch as it is an insect secretion. True gums, as distinct from varnish gums, are related to sugars and carbohydrates; they are soluble in water, insoluble in organic liquids, and on heating decompose without fusion. They differ from glues in that they are soluble in cold water. Varnish gums, on the other hand, are resinous materials related to terpenes and essential oils; they are soluble in oils and organic liquids, insoluble in water, and on heating generally melt, decompose, and become more readily soluble. Although the tendency has been to decry the use of the word gum for varnish resins, the term is too well established to be eradicated. Moreover, there are certain natural products that take on the properties of both gums and varnish resins. From Indian frankincense or olibanum, a water-soluble gum has been isolated as well as terpenes and a resinlike product.

Natural varnish resins, as has been noted, can be recognized by their transparency and translucency, their brittleness and conchoidal fracture, and their brown or yellow coloration. As a rule they possess no taste or smell in the solid state, but on heating they melt and often give off a distinctive odour; on burning they yield a smoky flame. Certain of these gums will dissolve directly in various organic liquids such as alcohol or turpentine. In dispersing the more insoluble resins in oils, it is necessary to preheat the resin—a process referred to as running or sweating. No generalization can be made concerning the chemical changes that occur during the running operation, but complex and deep-seated chemical rearrangements such as cracking, decarboxylation, and dehydration are involved. All of these changes are accompanied by a loss in weight; it is by such heat treatment that the resins become more readily dispersible in oil.

Solubility and hardness are the chief criteria used to classify resins, and on the basis of solubility they can be divided into spirit-soluble and oil-soluble types. Many new powerful organic solvents have been developed for the preparation of cellulose lacquers, and a number of these liquids can likewise be employed in the preparation of solutions of natural resins.

A. SPIRIT-SOLUBLE RESINS

1. Balsams.—Balsams are resins of a fluid character and are chiefly used in healing preparations. Certain of the more aromatic varieties have been incorporated into incense. Balsams are gen-

erally considered to be solutions of resins dispersed in benzoic or cinnamic acid esters, whereas oleoresins are considered to be solutions of resins in essential oils. However, it is difficult to draw a rigid distinction between balsams and oleoresins, although the latter are usually considered to be slightly more fluid. Canada balsam, an oleoresin derived from *Abies balsamea* and used in cementing lenses, is not a true balsam in that it does not contain benzoic acid or its ester. Certain of the true balsams are the balsam of Tolú (Colombia), the balsam of Peru, as well as the Sumatra (Indonesia) and Thailand benzoins and storax. The storax balsam is of particular interest from the standpoint of synthetic resins, since it was from this material that M. Bonaster in 1831 first isolated styrene, and doubtlessly this product arose through decarboxylation under heat of the cinnamic acid present in the balsam. Another variety of balsam is derived from the grass trees (*Xanthorrhoea*) of Australia. The most important varieties are the yellow and red types, often referred to as accroides gum. This resin contains phenolic bodies that appear to possess some medicinal values, particularly for treating infections of the mucous membranes.

2. Turpentines.—Various oleoresins (solutions of resins dispersed in essential oils) are known as turpentines. Venice turpentine is a pale green, viscous liquid which is collected from the larch (*Larix decidua,* or *europaea*). A liquid of lemonlike odour known as Strasbourg turpentine is derived from *Abies alba,* whereas Bordeaux turpentine is an oleoresin derived from the *Pinus pinaster.* The chief American varieties yielding oil of turpentine are the loblolly pine, *P. taeda,* and the slash pine, *P. caribaea.* On evaporation of the oleoresin a solid resin results, together with a volatile component (spirit of turpentine). The residue from distilling Bordeaux turpentine is known as Burgundy pitch and is used in medicinal plasters.

3. Mastic.—Mastic, a soft resin melting at about 105° C (about 221° F), is derived from the tree of the *Pistacia* genus, which grows in the islands of the Greek archipelago. When dissolved in turpentine, it is used as a varnish for the protection of paintings; when dispersed in bodied linseed oil, it is known as megilp and is used as a colour vehicle.

4. Dragon's Blood and Gamboge.—Dragon's blood is a black-brown resin in bulk, but in thin films it is transparent and of a deep crimson-red colour. The resin is found on the fruits of the rattan palm growing in the East Indies. It is soluble in alcohol and benzene, but not in ether or turpentine. The resin has been used as a varnish for violins and as a dye to colour spirit varnishes a deep red. Another resin used as a colour vehicle and in medicine is gamboge.

5. Dammar.—Dammar, one of the harder resins, is usually secured in the form of clear, pale yellow beads, melting at about 140° C (about 284° F). Various other coloured varieties are obtained from the *Agathis alba,* which is indigenous to Malaysia and the East Indies. The resin is insoluble in alcohol but dissolves in both aliphatic and aromatic hydrocarbons. Excellent varnishes can be made from these solutions, and the resulting films have a light colour and a good lustre. The resin is also readily soluble in oils without preliminary thermal processing. This resin in combination with nitrocellulose made possible the formulation of rapid-drying lacquers.

6. Sandarac.—The cypress pine, *Callitris,* which grows in Australia, North Africa, and North America, produces the hard resin called sandarac, which is soluble in alcohol as well as in the more powerful lacquer solvents. The resin melts at 150° C (about 302° F) and is used as a spirit varnish for coating paper, leather, and metal. Although the initial film is brittle, it can be readily modified to yield elastic films by the addition of elemi, an oleoresin.

7. Lacs.—Shellac has been considered a zoochemical substance, inasmuch as it is a secretion of an insect known as *Laccifer lacca.* The term shellac has been used incorrectly to cover generically all of the lac products. Insects growing on certain of the trees of the genus *Acacia* produce a scaly substance known as stick lac. This material is ground, washed, and filtered hot, the filtrate passing onto water-cooled drums from which it is removed in the familiar flakelike form. The button lac is a lac which has been allowed to fall on a flat surface. Lac is one of the widely used resins in industry. It is also used in electric insulation, as a coating for wood and metal, and as a binding agent for molding composition. Certain varieties are incorporated into sealing waxes.

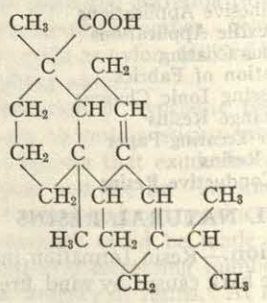
Chemically, shellac consists of a mixture of polyhydroxy acids. Two varieties have been isolated, one a hard lac and the other a softer material that appears to act as a plasticizer for the harder component. The softer portion consists primarily of uncombined acids, whereas the harder material consists of polyesters. A major portion of the hard lac was found to be a monobasic ester that could be made to undergo hydrolytic fission to aleuritic acid and lacollic lactone. Other acids which have been isolated from shellac are a tetrahydroxy acid known as kerrolic acid, as well as shellolic acid, together with a natural yellow dyestuff known as erythrolaccin. Aleuritic acid is considered to be 9,10,16-hexadecanetriol acid: $HOCH_2-(CH_2)_5-(CHOH)_2-(CH_2)_7-CO_2H$. Although the solubility of shellac is usually associated with alcohol, it is also dispersible in aqueous solutions. There appears to be some indication that on long standing alcohol may react with shellac. A white variety can be made by a bleaching process from which colourless, transparent lacquers can be made.

B. Oil-Soluble Resins

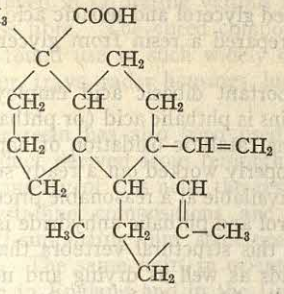
1. Rosin.—Upon distillation of the oleoresin from the long-leaf pine two materials are obtained: one a volatile component (spirit of turpentine) and the other a nonvolatile, resinous residue (rosin). The word rosin is used for this product, rather than resin because the latter is a term used generically to cover all of the compounds of this type. Depending on the source of the oil of turpentine, it is possible to have either gum turpentine and gum rosin or wood turpentine and wood rosin; the former variety originates from the turpentine secured by tapping the trees. By solvent extraction of the stumps, wood rosin is obtained, and this is generally of a darker colour. Various designations are employed to distinguish the colour of the product. The colour of French rosin is designated by the letter A, and the greater the number of A's used the paler the grade. The U.S. designation is more arbitrary, and the better classes are known as WW (water white) and WG (window glass). Rosin is a brittle resin that powders readily and becomes sticky when warm. Its specific gravity is about 1.070 to 1.080, and it dissolves in the usual organic liquids. Rosin is also known by the name of colophony or colophonium (from the Greek *kolophonios*).

At one time much of the rosin was used untreated, but the trend is to subject it to chemical processing. The chief constituent of rosin is an acid known as abietic acid, and many of the uses of rosin are dependent upon its acidic properties. Combined with alkalies or with metallic oxides, soaps are obtained. The sodium soap is water dispersible and is employed in sizing paper. Sodium abietate is mixed with other alkali soaps in the manufacture of laundry soap. The lime and zinc salts find use as so-called gloss oils in the paint industry, whereas the metallic soaps derived from lead, cobalt, and manganese are used as driers in paints and varnishes. When rosin is esterified with glycerol (glycerine), the resulting product is known as ester gum. Somewhat harder esterification products are made through a conjoint ester of rosin with glycerol and with phthalic anhydride. Partial decarboxylation of acid occurs when rosin is heated to elevated temperatures; such products are known as rosin oils.

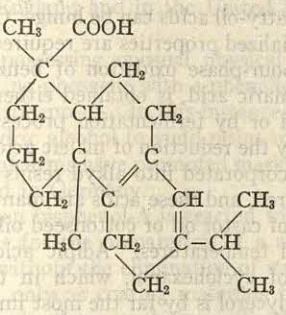
The acids isolated from rosin include abietic acid,



pimaric acid,



and laevopimaric acid,



It will be noted that certain of these acids appear to possess a system of conjugated double bonds, which may account for the ease with which rosin oxidizes when it is exposed to air. By chemically combining rosin with hydrogen it is possible to obtain a product that exhibits greater stability and is less subject to discoloration on storage. The abietic acid in rosin can be made to undergo hydrogen disproportionation leading to the so-called dehydrogenated rosin. This type of chemically modified rosin, as the sodium soap, was used extensively during World War II as the emulsifying agent in the preparation of synthetic rubber. The properties of the modified rosin were such that it could be allowed to remain in the coagulated rubber. Hydrogenation and disproportionation both cause rosin to crystallize more readily, and consequently the hydrogenation is carried only to the point where satisfactory stability can be secured without crystallization. By combining rosin chemically with certain unsaturated types of dibasic acids, such as maleic and fumaric acid, it is possible to destroy the unsaturation without inducing crystallization. It is probable that the character of the varnish made from China wood oil and the rosin derivative may reside in the chemical combination that takes place between the unsaturated components of both products.

2. Copals.—The copals form an important group of varnish resins. The word copal appears to have been derived from the Spanish or Mexican word *copalli* ("incense"). Various types of products are known—the recent varieties as well as the fossil types. Soft Manila copal is readily soluble in organic solvent liquids and in oils or, as in the case of the pontianak variety, it requires running before it can be dispersed in oil. Several varieties are employed in the varnish trade: kauri copal, melting at about 150° C (about 302° F), is derived from the New Zealand pine; Congo copal originates in the Congo; while Zanzibar (East African) copal is dug from the coast of the mainland opposite the island of Zanzibar. Some of the South American copals derived from Brazil and Colombia have attracted some attention. Copal has been esterified with glycerol in a manner similar to that employed in making ester gum. Because of the high melting point of the copal gum, it is necessary to conduct this thermal decomposition to a point much further than is customarily employed when the resin is to be dissolved in oil, and temperatures as high as 330°–340° C (about 626°–644° F) are employed. Two acids have been isolated from Congo copal; one is the dibasic congocopalic acid, $C_{36}H_{58}(COOH)_2$, and the other is the monobasic congocopalolic acid, $C_{27}H_{32}(OH)COOH$.

3. Amber.—Amber, the hardest natural resin known, finds little use in the varnish industry because of its lack of solubility. When it is incorporated in oil, so much discoloration takes place during the running operation that the resulting varnish has a poor colour. The resin is found in the so-called blue earth, in East Prussia in the Baltic region. The fact that it is derived from a variety of *Pinus* indicates that over a sufficiently long period of time under appropriate conditions an oleoresin can be converted into a heat-infusible product. Amber is used chiefly for fabricating beads and other items of jewelry. In certain respects amber can be handled in much the same manner as that used in the fabrication of cast plastics.

4. Oriental Lacquer.—Oriental lacquer is a distinct product derived from *Toxicodendron vernicifluum,* a tree indigenous to China. The manufacturing process was introduced into Japan and remained secret for centuries. A milklike emulsion secured from the tree is concentrated by evaporation to a viscous liquid resembling a bodied oil. When this is applied as a thin film, it hardens in about a day to form a tough skin. The composition is peculiar in that it will dry only in a dark, moist atmosphere; when exposed to light and warmth, the varnish remains tacky. The varnish contains a skin irritant, and this material may be the urushiol which is similar to a product isolated from the *Toxicodendron radicans* (poison ivy).

5. Cashew-Shell-Nut Oil.—Another product containing phenolic bodies is derived from the nuts of the cashew tree (*Anacardium occidentale*); the oil known as the cashew-shell-nut oil possesses materials which lead to vesicant action (blistering), but by appropriate chemical treatment the irritant is destroyed. This product has found some commercial importance in the United States.

II. SYNTHETIC RESINS

1. Characteristics and Usage.—Synthetic resins, while possessing most of the physical characteristics of natural resins, have many unique properties of their own. Chemically there is a certain degree of resemblance between the synthetic resins of phenol-formaldehyde and the natural phenolic resins found in Oriental lacquer and in accroides gum. Moreover, one can trace a certain amount of resemblance between the polyester resins known as alkyds and the polyesters found in shellac. Although it has usually been considered that the synthetic resins possess the unique characteristic of becoming insoluble and infusible on heat treatment, it is known that shellac will become insoluble on prolonged heating, and the same phenomenon has been observed with certain of the other gums.

The synthetic resins are of industrial interest not only as substitutes for natural resins in the coating industry but also because they find extensive use as adhesives, textile impregnants, binders, as agents for removing ions from water solutions, and as binders in the plastics molding industry (*see* PLASTICS).

2. Classifications.—Physically it is possible to classify synthetic resins according to their solubility. There are those resins which remain permanently soluble and those which are initially soluble but become insoluble and infusible under the action of heat. The first type is known as the thermoplastic type of synthetic resin, whereas the latter is known variously as heat hardenable, thermosetting, or thermocuring resins.

The permanently soluble or thermoplastic resins consist of molecules that are more or less linear in form. During solution in an organic medium, the solvent penetrates within the threadlike molecule; irrespective of the size of the resin molecule, solution will eventually occur. Under the influence of heat the threadlike molecules can be forced to move, and on cooling the impressed form is retained. On the other hand, the thermosetting resins consist of resinous molecules that are tied together three-dimensionally into a network pattern. In the initial stages where the network is small, the solvent can readily penetrate the interstices of the network, but after chemical combination has taken place and a large three-dimensional network is formed, the resin becomes insoluble. Since the network is tied together rigidly, the resulting molecular structure is infusible.

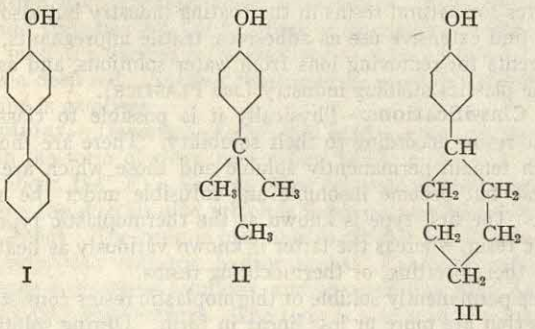
Two main classes may be distinguished under chemical classification: (1) the condensation resin, such as the phenol-formaldehyde or melamine-formaldehyde type, in which the molecules unite with the elimination of water; and (2) the polymerization resin, in which chemical reaction takes place through loss of unsaturation, without the evolution of any low-molecular-weight material.

A. Coating Resins

1. Phenol-Formaldehyde Resins.—The chemical combination of phenols with aldehydes was noted by many investigators in the 19th century. Among the organic chemists who had studied the reaction were C. F. Gerhardt (1853), Adolf von Baeyer (1872), and A. Michael (1883), but it was only after the advent of cheap formaldehyde in 1891 that a more extensive investigation was made toward the commercial applications of this resin. Various investigations were made by W. Kleeberg, A. Smith, and A. Luft, and certain of the methods employed resembled the technology that had proved successful with thermoplastic nitrocellulose plastics but which failed when extended to thermosetting compositions. The first successful work in this field was carried out by L. H. Baekeland. Through a study of the various stages of resinification and through the utilization of a so-called bakelizer, he was able to mold many products, many of which were used in electrical goods. Meanwhile, the possibility of employing this condensation product to replace shellac in phonograph records was considered by J. W. Aylsworth, and the manufacture of phenolic resins was started as a result of the studies of L. V. Redman.

In spite of the marked commercial success of these resins in molding, in casting, and in laminating, they were not suitable for coating compositions. While it was possible to make a phenolic varnish for laminating purposes, this varnish could be dissolved only in alcohol and could not be dispersed in cheap solvents or in drying oils. The first successful attempt to use phenol-formaldehyde resins directly as substitutes for natural resins in coating compositions was the result of the work of K. Albert of Germany. He found that by a preliminary heating or fluxing of the phenol-formaldehyde resin with rosin, it was possible to disperse the resulting mixture in drying oils. These products, when dispersed in China wood oil, possessed rapid drying characteristics and formed films possessing good durability.

In 1928 the first so-called oil-soluble phenolic resin appeared on the market. Through the use of appropriately substituted phenols and the combining of such substituted phenols with formaldehyde, it was possible to obtain a resin which was directly soluble in oil without preliminary fluxing with rosin. These oil-soluble phenolic resins found wide acceptance in the varnish field. Among the phenols useful for such purposes are phenyl phenol (I), tertiary butylphenol (II), and cyclohexylphenol (III), as well as certain



I II III

tar acids which boil in the xylenol range. The resins are incorporated into the oil by adding resin in increments at a rate at which frothing can be controlled. The temperature then is raised until satisfactory increase in viscosity occurs. The European procedure favours the addition of the resin to the pretreated oil, and, while it appears to yield lighter coloured and less viscous products, the resulting films appear to be less resistant chemically. Other combinations are known, certain of which consist in substituting an alkyd resin for a part of the drying oil. Durable finishes have been made from alkyd-phenol-formaldehyde oil combinations.

2. Alkyd Resins.—These resins are reaction products of polyhydric alcohols and polybasic acids, and various modifications can be made by adding monohydric alcohols or monobasic acids to the polyester composition. The derivation of the term alkyd becomes apparent when it is pointed out that the "cid" from acid was changed to "kyd" for the sake of euphony. J. J. Berzelius prepared glycerol tartrate in 1847; J. M. van Bemmelen prepared a resin by reacting succinic acid with glycerol in 1856; M. P. E. Berthelot esterified glycerol and sebacic acid in 1854; while M. A. von Lourenço prepared a resin from glycerol and citric acid in 1863.

The most important dibasic acid employed in the manufacture of alkyd resins is phthalic acid (or phthalic anhydride), which is obtained by the catalytic oxidation of naphthalene. Once this synthesis was properly worked out a ready source of this valuable commodity was available at a reasonable price. While the reaction product of glycerol and phthalic anhydride is of limited utility by itself, it is upon this structural vertebra that such ingredients as natural resin acids as well as drying and nondrying varieties of vegetable fatty-oil acids can be hung. Other dibasic acids are used where specialized properties are required. Maleic acid is obtained by the vapour-phase oxidation of benzene, while its geometrical isomer, fumaric acid, is obtained either by rearrangement of the maleic acid or by fermentation processes. Succinic acid can be prepared by the reduction of maleic acid. Sebacic acid and azelaic acid are incorporated into alkyd resins where exceptional flexibility is required, and these acids are manufactured commercially by treatment of castor oil or cottonseed oil, respectively, with caustic at elevated temperatures. Adipic acid is also available by the oxidation of cyclohexanol, which in turn can be derived from phenol. Glycerol is by far the most important polyhydric alcohol used, but ethylene glycol, diethylene glycol, and pentaerythritol are used for merits of their own.

The drying-type alkyd resins first came into commercial prominence when it was demonstrated by R. H. Kienle that it was possible to form a new type of product by recombining the component parts of a drying oil, that is, the glycerol and the drying-oil acid in the presence of a saturated dibasic acid such as phthalic. Under these conditions the co-condensation of glycerol, phthalic acid (as anhydride), and a drying-oil acid yielded a high-molecular-weight, resinous condensation product in which the unsaturation of the drying-oil acid was substantially unimpaired. The result was that the resin would dry in a manner similar to the natural drying oil. Such resins in organic liquids yield solutions that resemble varnish and can be used as such. Since the resins could be dispersed in relatively cheap organic liquids, these varnish solutions found wide acceptance for coating various metals and as priming paints and enamels. They are used to finish automobiles, streetcars, and railway coaches and, because of their good chemical resistance are used as enamels for coating refrigerators and washing machines. Similar resin solutions are used in ornamental hardware; for coating metal furniture, metal signs, and farm equipment; and, because of good heat resistance, for coating radiators, smokestacks, and light reflectors. They find wide acceptance as architectural enamels, traffic paints, and as printing-ink ingredients.

These resins are often used alone, but they show excellent compatibility characteristics with a wide variety of other film-forming agents, such as nitrocellulose, natural resins, phenolic resins, and urea- and melamine-formaldehyde resins. With nitrocellulose it is possible to secure films possessing toughness, hardness, durability, as well as good gloss. It was this combination with nitrocellulose and alkyd resins which initially permitted the formulation of automotive finishes possessing an enamellike quality and excellent outdoor durability. When these resins are modified with natural resins, the melting point and hardness are increased; since such compositions release solvent very readily, they are used as rubbing and sanding vehicles. When mixed with urea-formaldehyde and melamine-formaldehyde condensation products, the alkyd resin becomes harder and more mar-resistant.

3. Polyester Resins.—While closely related to alkyd resins, the polyester materials differ from the conventional alkyd resins in that the cure is associated with a low-molecular-weight unsaturated organic liquid. The polyester resins, or anhydrous thermosetting resins, usually comprise an unsaturated alkyd resin prepared from a polyhydric alcohol with an unsaturated acid such as maleic or fumaric acid. This alkyd resin is then dispersed in an organic liquid such as monomeric styrene or with diallyl phthalate. This solution, appropriately stabilized for shipping, is treated with a peroxide catalyst just before use. The catalyzed resinous

material is then employed in saturating various fibrous materials such as fabric or glass fibre. The cured composite structure of resin and glass fibre found use in such widely differing applications as plastic armour, trays, radar housings, luggage, and lightweight boats.

The term polyester resin has also been used for an entirely different type of product derived from terephthalic esters. Because of the high symmetry of this acid, the resulting polyesters are high-melting crystalline compositions and, when properly oriented, form a self-supporting film structure of high transparency and strength. The same resin, in oriented fibrous form, finds application both in England and in the United States as a textile fibre.

Still another polyester possessing unusual physical properties has been prepared by reacting phosgene with a phenolic substance commonly designated as bisphenol-A. In this instance the phenolic body serves as the dihydric alcohol to yield resins of outstanding toughness. A number of firms have promoted markets for this product, initially developed in Germany.

4. Epoxy Resins.—When bisphenol-A is reacted with epichlorohydrin, one has the basis for the preparation of a curing resin where the reaction occurs without the elimination of water. Such resins have been used not only as coating materials but as potting compositions. Currently they are being utilized as textile finishes.

5. Urea-Formaldehyde Resins.—The chemical condensation of urea and formaldehyde yields resins of great value in both the molding and coating industries. The resins are characterized by extremely light colour, and products fabricated from such materials can be made into colourless moldings. The fundamental chemical investigations of Hanns John laid the foundation for the use of this resin in the plastics industry; but insofar as coating resins are concerned, it was the observation of Kurt Ripper that proved most valuable. He found that under suitable conditions the water-soluble condensation product of urea and formaldehyde could be dispersed in organic liquids. To make the resin soluble in varnish solvents for coating use, it was first necessary to conduct the condensation of urea and formaldehyde in a solvent such as alcohol and then to remove the water of condensation as an azeotrope with the alcohol. The resin thus formed in alcoholic solution could then be diluted with aromatic solvents.

By themselves, films and coatings of the unmodified urea resins are hard and marproof and possess good colour and gloss but lack distensibility. From the standpoint of their use in enamels the resins are neutral, and consequently any type of pigment can be admixed with them. When these urea resins are blended with alkyd resins, they become flexible and adhere to metal surfaces. This combination of urea-formaldehyde resins and alkyd resins is in many ways a unique combination whereby the urea resins improve certain deficiencies of the alkyd resins, such as increasing hardness and eliminating the tendency of the oil-modified alkyd resins to wrinkle on rapid drying. The urea-formaldehyde resins under the influence of heat contribute hardness, colour, and gloss to the cured film, while the alkyd resins produce flexibility, drying ability, and adhesion to metal surfaces.

6. Melamine-Formaldehyde Resins.—Many of the excellent characteristics exhibited by the urea-formaldehyde resins in coatings are also shown by the melamine-formaldehyde resins. Melamine, or polymerized (trimerized) cyanamide, is a heterocyclic compound which reacts and cures rapidly in combination with formaldehyde. Unlike urea, which is low melting and soluble in water, melamine possesses a high melting point (354° C, or about 669° F) and dissolves very slightly in water. It is characterized by an exceptionally stable ring system of alternate carbon and nitrogen atoms—a stability reflected in the resins made from it. The melamine and formaldehyde resin can be dispersed in organic solvents by procedures similar to those employed for the urea-formaldehyde condensation product. When used in admixture with alkyd resins a much faster heat cure can be secured than when urea-formaldehyde is used. The outstanding characteristics which urea resins supply to films are further enhanced with melamine resins; these are superior in resistance to various chemical reagents, in outdoor durability, and in colour retention on exposure to both heat and light. These properties, in addition to porcelainlike appearance and resistance to abrasion, enabled such finishes to enter into automotive coatings and industrial finishes.

7. Polyethylene.—While most uses of polymerized ethylene are in moldings and self-supporting films, there are certain newer developments whereby the thermoplastic product is converted to a thermosetting variety. When the polymer is exposed to radiation, such as the γ-rays, a certain amount of hydrogen is knocked out of the system, and under appropriate conditions, depending on whether the polymer is in aerobic or anaerobic environment, the fragments will reunite to form an insoluble product. This infusible material possesses about the same electrical characteristics as the unmodified material. When this radiation is performed in the presence of polyethylene that has been milled with carbon black, an infusible, filled, molded composition is obtained.

Closely allied to polyethylene is polypropylene, but the preparation of this polymer requires wholly different catalysts from those used in the ethylene reaction.

8. Coumarone-Indene Resins.—From the light oils present in the distillation of coal tar, it is possible to secure a fraction rich in indene, coumarone, and related isomers. This mixture can be polymerized by means of sulfuric acid into resins of soft or hard consistency. These synthetic resins are among the oldest-known synthetic products and have been available from the time of the initial investigations of G. Kraemer and A. Spilker in 1890. The resins exhibit good compatibility characteristics with a wide variety of other polymeric products, both synthetic and natural, and have been used in coating concrete, in the manufacture of antifouling ship-bottom paints, as additives to paraffin wax, in admixture with bitumens, and as compounding agents in butadiene-styrene synthetic rubber.

9. Silicones.—The silicone resins are based on the silicon-oxygen skeleton rather than the carbon-oxygen chains or the carbon chain found in the conventional resins. This siloxane linkage, as the silicon-oxygen combination is called, introduces a degree of resistance to heat that is not found in those chains possessing carbon atoms exclusively. Naturally, those same reagents which can break the silicon-oxygen bridge in silicate minerals are also instrumental in causing the silicone resins to undergo cleavage; both hydrofluoric acid and strong caustic will cleave the siloxane chain in the silicone resins. Through the proper choice of ingredients, groupings can be introduced into the molecular structure whereby growth may be made to occur essentially linearly as, for example, through the introduction of saturated dialkyl-siloxy groups, or three-dimensionally through the utilization of the monoalkyl-siloxy groupings.

Various silicones can be made by changing the nature of the alkyl group, but most of the commercial production is restricted to the methyl silicones. Various polymeric structures have been made, certain of which are viscous liquids, others resinous, and even rubbery products have been produced. The liquids have found use as hydraulic oils and as instrument and transformer oils. Some of the higher-molecular-weight materials have found further application as varnishes as well as in high-temperature-resisting paints and enamels and as coatings for electrical insulation. When applied to the surfaces of glass or ceramics and baked, the silicones yield water-repellent surfaces.

10. Fluorine Resins.—Even though elementary fluorine is a relatively reactive gas, when this element is united with carbon in the form of an unsaturated monomer and then polymerized, compositions of remarkable heat and chemical resistance are formed. Compositions are commercially available where only carbon and fluorine exist in the polymer matrix, but in certain instances chlorine may replace a portion of the fluorine. Two resins that have achieved the greatest success are the tetrafluoroethylene polymer and trifluorochloroethylene derivatives. In certain instances modification has involved the use of perfluorinated propylene. While most applications are directed toward plastics, outstanding coatings and fibres have been prepared from these compositions. Because polytetrafluoroethylene possesses an extremely low coefficient of friction, it has been used in the fabrication of

composite metal bearings. Even when only one surface is coated, friction is reduced. Through the use of fluorinated diolefins, heat-resistant rubber compositions have been formulated.

11. Polyamides.—By substituting diamines in place of diols and conducting the condensation with dibasic acids at elevated temperature polyamides may be secured. To insure crystallinity, symmetrically structured acids and amines are employed, such as adipic acid and hexamethylenediamine. Amino acids such as aminocaproic acid may be condensed to high-molecular-weight derivatives, or the internally dehydrated product, caprolactam, may be polymerized to similar types of polyamides. Fibres from these polyamides are known as nylon, but the same polymer can also be fabricated into sheets, coatings, and rods. It is important to select ingredients that avoid imide formation, but these imides have found applications in condensation products known as polyimides, which are resin systems stable at elevated temperature. Polyimide-based resins are marketed as insulating varnish, wire enamel, and glass-coated fabrics. Because the polyimides possess high thermal stability and good electrical and mechanical properties, together with radiation resistance, they are desirable for use in aerospace applications. Polyimides are produced by condensing a dianhydride of an aromatic tetrabasic acid, such as pyromellitic anhydride, with an aromatic diamine. There have also been developments on the reversed type of product. These polymers are formed from aromatic tetramines and dibasic acids, the polybenzimidazoles. When the dibasic acids are aliphatic, the heat resistance is not as outstanding as when aromatic acids are used in the condensation.

12. Polyurethanes.—These products masquerade under a variety of names, such as urethanes, isocyanate polymers, and polyurethanes, but these names are expedient rather than accurate. While polymers can be prepared by polymerizing isocyanates, polyurethanes are not derived by polymerizing a monomeric urethane molecule. Commercial polyurethanes encompass a variety of oils and resins, such as castor oil, polyesters, and polyethers which have been combined chemically with di- and triisocyanates. The reaction was initially studied in Germany by Otto Bayer in 1937 in an effort to prepare a product competitive with polyamides by reacting diamines with diisocyanates. While these polyureas were used for some time in Germany, they were not accepted at first in the United States. Extensive studies were conducted during World War II in the preparation of foams, adhesives, and coatings. While isocyanates had been employed in the United States for bonding rubber to metal, the full commercial impact of the new structures was not appreciated until after the war, when the scientific teams studying German developments reported their findings. Nevertheless, commercial interest in these materials grew slowly until machinery was developed for continuous production methods in manufacturing flexible foams. Initially, polyester resins were employed as the principal complementary component, but it was the advent of less expensive polyethers derived from the polymerization of propylene oxide which boosted these products to large volume uses. Flexible foam was found to be superior to foam rubber, but now major attention is directed toward rigid formulations, particularly for insulation. The latter development has been aided by techniques for introducing gaseous fluorocarbons as an integral part of foam architecture. The presence of this fluorocarbon in the intracellular spaces insures highly effective insulation.

13. Polyethers.—The polyether component in polyurethane systems, as well as its lower homolog polyethylene oxide, is characterized by an oxygen bridge as an integral part of the polymer chain. A simple, different type of polyether may be prepared by polymerizing vinyl ethers such as methyl vinyl ether as well as other vinyl ethers derived from higher alcohols by reaction with acetylene. Polyvinyl methyl ether is produced not only as a high polymer in the atactic form but also in a stereoregular isotactic variety.

14. Acetal Resins.—Polyvinyl butyral, used in safety glass, and polyvinyl formal, used as wire enamel, both fit under the term acetal. Most frequently, however, acetal resins refer to high-molecular-weight, stable linear polymers of formaldehyde. Because of the insoluble nature of these acetal polymers, they are used most frequently as molding and extrusion compositions.

B. Resin Adhesives

1. Plywood Adhesives.—Prior to the introduction of synthetic resins for plywood construction, laminated wood was susceptible to deterioration by water and high humidity. The natural protein products such as albumin and casein could not be rendered insoluble to the same extent as later became possible with various condensation products such as phenol-formaldehyde, urea-formaldehyde, and melamine-formaldehyde resins. The new resin adhesives permit the construction of plywood in which the glue line is strong, resistant to water, and immune to attack by the action of fungi, molds, and vermin. Such plywood can be used not only for architectural and automotive purposes but also for aeronautical and marine construction. Phenolic-resin adhesives became commercially available about 1935; urea condensation products were introduced about 1937.

Two types of synthetic glues are manufactured—cold-setting and hot-setting. Certain resins are supplied in powder form requiring solution prior to use, whereas other types are already dispersed in a liquid medium. Extenders such as cereal flour and wheat flour are sometimes employed where maximum strength and waterproofness are not essential. Phenolic resins yield an especially durable bond, but the resin is coloured, and the colour may bleed through thin veneers. Such colour is also a disadvantage where the glued edges are exposed. The urea resin is characterized by a rapid cure at low temperature and is widely employed in the preparation of cold-setting adhesives. The urea resin, moreover, is colourless and will not change the colour of the wood. Melamine resins likewise possess excellent colour characteristics, and the glue line formed from them is resistant to both cold and boiling water.

Keeping pace with the development of new adhesives were new fabricating and molding techniques that allowed construction of complicated shapes, particularly in aeronautics and boat construction. Flat sheets can be "post-formed" into simple curves, but for construction of compound curved surfaces a molding procedure is preferred. This is accomplished by applying the glue of the veneers and allowing them to dry in order to permit easy handling. A mold is constructed with the exact contours needed in the finished assembly, and the coated wood veneers are placed in the mold and fastened by staples. The laminates are enclosed in a rubber bag which is evacuated in order to keep the veneers rigidly in place, and the assembly is placed in an autoclave and heated in order to render the resin insoluble and infusible. Such procedures enabled rapid construction of large aircraft parts, pontoons, and motor torpedo boats.

2. Wood Impregnation.—Wood that has been subjected to reduced atmospheric pressure to remove occluded air can be impregnated with various resin solutions dissolved in water or in alcohol. After drying, the temperature is raised, whereupon curing of the resin occurs in the interior of the wood, rendering it harder, stronger, and more resistant to water and water vapour. By adding appropriate accelerators prior to impregnation the cure can be effected at a lower temperature with less damage to the structure of the wood. Phenol formaldehyde, urea formaldehyde, and mixture of the two resins have been employed for this purpose.

3. Other Adhesive Applications.—Many other resinous and rubbery compositions, dispersed in water or dissolved in organic liquids, are used to bind metals, plastics, glass, rubber, paper, brickwork, leather, fabrics, and cork. Others are used in the manufacture of shoes, gaskets, furniture, lighting assemblies, sound insulation, and upholstery. Certain adhesives have natural or synthetic rubber as a base, whereas others contain synthetic thermoplastic and thermosetting resins. During World War II the reinforcement of starch by urea-resin adhesives in paperboard manufacture led to paper containers having a high resistance to water.

C. Resins for Textile Applications

1. Continuous Coating.—One method of separating electrical conductors is by using a covering of cotton or silk. As long as anhydrous conditions exist, such insulation is satisfactory, but in

a humid atmosphere the textile absorbs water, and its insulating efficiency is markedly decreased. To overcome this disadvantage, the dried fabric is treated with a varnish subsequently cured, thereby sealing the fabric. The varnish selected is such that water-vapour transmission through the film of resin will be as small as possible. Of those resins used, the phenolic resins are the best known, although almost every type of natural and synthetic resin has been tested for this type of insulating varnish.

2. Impregnation of Fabrics.—Resins are applied to fabrics for purposes other than insulation—for instance, to improve the finish of cotton and rayon and to render them nonshrinking and crushproof. Resins have also been employed to bind pigments to the fabric, to minimize bleeding and crocking of dyes, and as mordants for dyeing cellulose fibres with wool dyes (animalized cellulose). Since no resin discoloration can be tolerated in uses of this type, the thermosetting resins having widest acceptance are the urea-formaldehyde condensation products. In numerous applications, superior results can be secured only with the melamine-formaldehyde resins. The more notable achievements of the latter resin include shrinkage control of cotton and wool, improved crease resistance of cotton and rayon, production of durable glazes on chintz, treatment of binders to prevent thread slippage, and minimized gas fading of acetate colours. Many of these effects are achieved by treating textiles with low-molecular-weight, water-soluble condensation products and then causing resin formation to occur on the fabric.

Quite different effects are obtained by using high-molecular-weight, water-insoluble thermoplastic resins which are dispersed in water. Such resins render the fabric stiff, crisp, and full, and when properly formulated such properties are not destroyed by laundering. Other thermoplastic resins impart good draping characteristics and improve the abrasion resistance of the textile, whereas still others are employed for upholstery finishing, raincoats, shower curtains, and other waterproofing applications.

Through suitable modification of resinous ingredients, particularly through the use of phosphorus or compounds of phosphorus and halogen, it has been possible to devise cotton finishes having substantial resistance to flame. This does not imply that the fabric is fireproof, but when the appropriate phosphorus compounds are combined chemically with cellulose, such materials will yield water and carbon at elevated temperatures. When the flame is removed, the charred cellulose will not propagate combustion, and there is no flaming or afterglow.

D. Resins Possessing Ionic Charges

1. Ion-Exchange Resins.—By the introduction of strong acid groupings such as carboxyl and sulfonic acid into a three-dimensional polymer, high-molecular-weight resins can be made where the resin is ionic in character and where the ion is chemically bound in the resin molecule. These ionic resins in the form of sodium salt can be used as a means of softening water whereby the calcium ions of the hard water are replaced by the sodium ions from the resin. In this respect the synthetic ion-exchange resins, generally known as cation resins, behave like the natural zeolites, and, like the zeolites, the resins used under such conditions do not change the amount of dissolved salt in the water.

Condensation products can also be prepared synthetically where basic groupings such as amino- and guanido- are bound in the resin molecule, and these so-called anion resins can replace anions. It follows that a combination of the acidic and basic resins or a cation and an anion resin can completely eliminate the mineral content of water by first allowing the cation-exchange resin in the form of a free acid to react with the salt and subsequently reacting the effluent with an anion exchanger.

Once the resins become saturated with minerals, they can be regenerated chemically and used over again as often as required. The process works most expediently where the concentration of mineral matter is low, but the scavenging is so complete that the method has found favour not only in producing a so-called demineralized distilled water but in numerous industrial processes where the removal of ionic impurities is not possible by distillation. Ion-exchange resins have been used to remove mineral impurities from pharmaceutical preparations, dyestuffs, sugar, syrups, enzyme preparations, emulsions, glycols, and formaldehyde. Other industrial uses include the recovery of valuable metals and various other inorganic and organic materials from industrial wastes. The resins have also been employed as catalysts in chemical reactions, particularly in the inversion of sugar.

Water-soluble resins might most properly be designated as gums. The alternative nomenclature appears more attractive even though the definition distorts the initial distinction between resins and gums. Since the same raw materials are so closely allied with the resin industry, this terminology is useful to distinguish these synthetic products from the natural water-soluble gums. In the same way that resins may be modified, various water-dispersible functional groups may be introduced into the polymer molecule; these groups may be ionic or nonionic. By suitable adjustment a wide range of physical properties may be incorporated into the final polymer, permitting it to be more or less sensitive to accompanying ions. The carboxyl group is the preferred ionic residue, where this functional group is introduced using either acrylic and methacrylic acid or maleic anhydride. Of the nonionic residues, a much wider range of components are available, such as the alcohol group, methoxides, pyrrolidone, and amides. Considerable attention had been directed to various copolymers of acrylamide and acrylic acid. One of the newer outlets for these water-soluble colloids has been approved for removing the "chill haze" in beer. Polyvinylpyrrolidone will precipitate tannins and other complex proteins from beer and wine. The polymeric acids also have applications in a number of unusual outlets such as in soil stabilization and in drilling fluids containing mud. A number of soils are fine powders when dry and slimy muds when wet. If these soils are treated with a small concentration of these polymeric acids, the mud seems to dry up, yielding a friable soil that allows water to drain away without serious erosion. In drilling muds these polymeric acids allow the mud to retain water and prevent its loss into the pores or fissures of rocks where water loss might cause seizure of the drilling bit.

2. Resins for Treating Paper.—Another resinous ion which has attracted attention is the cationic melamine-formaldehyde resin. Unlike the ion-exchange resins, the cationic melamine resin is initially dispersible in water. The large ion is attracted toward and adheres to the cellulose fibre. It can be incorporated into paper as an acidic dispersion to a pulp suspension, and after migration to the paper fibre the resin becomes insoluble and infusible as the paper stock is dried. The resulting product is characterized by superior fold resistance and by a nonlinting behaviour when dry; when wet it does not disintegrate. Water-dispersible urea resins with ionic properties can be added to paper stock in a similar manner. While certain of these resins are anionic (*i.e.*, they contain sulfonic acid groups and are flocculated on the fibres through the use of aluminum sulfate), others are cationic and need no flocculation agent.

3. Ionomer Resins.—This term has been coined for a family of polymers comprising covalent and ionic bonds in high-molecular-weight form. By introducing ionic components into a semicrystalline structure, the crystallinity is depressed, but the modulus of elasticity, yield point, oil resistance, and solvent resistance are notably improved. The anions are carboxyl residues to which are attached various metallic cations such as sodium, potassium, zinc, and magnesium.

E. Electrically Conductive Resins

Semiconducting organic solids fall into two major classes, molecular crystals and polymers. The classical example of a molecular crystal is anthracene, which is possibly the most extensively investigated organic semiconductor. The semiconducting characteristics of polymers are not as well established as those of the molecular crystals. Nevertheless, carbon resistors, which have been in commercial production for many years, are a type of organic semiconductor system. An electrically conductive resin has been produced that may be a forerunner of a wide spectrum of similar products. This resin was produced by combining 7,7,8,8-tetracyanoquinodimethane with a poly-N-methylvinylpyridinium

derivative. This polymeric composition can be cast from organic liquids to form films where conductivity is electronic rather than ionic, and where values of 10^{-3} reciprocal ohm centimetres have been observed.

(E. L. KA.)

RESISTENCIA, a city of northeastern Argentina, capital of the province of Chaco (*q.v.*), is situated on the Barranqueras stream that connects with the Paraná River at Barranqueras, its port. Pop. (1960) 80,089. It is the administrative centre of the province and the nucleus of a zone of frontier settlement extending toward the northwest. Cotton, quebracho, leather, cattle, and lead are the main industries in the area. A railroad runs west to Metán and Rosario de la Frontera, and south to Santa Fe, 348 mi. distant.

(J. L. TR.)

REŞIŢA, a town in the Banat *regiune* (administrative and economic region) of western Rumania, is situated in a coal basin and a metalliferous region. Pop. (1960 est.) 46,008. Reşiţa is an important industrial centre, smelting the iron ore from Dognecea and Ocna de Fier. In the neighbourhood, coking coal is mined at Anina, Doman, and Secu. The Reşiţa iron and steel works, rebuilt under the Communist regime, operate blast furnaces, steel foundries, rolling mills, and metalworking and machine-building enterprises.

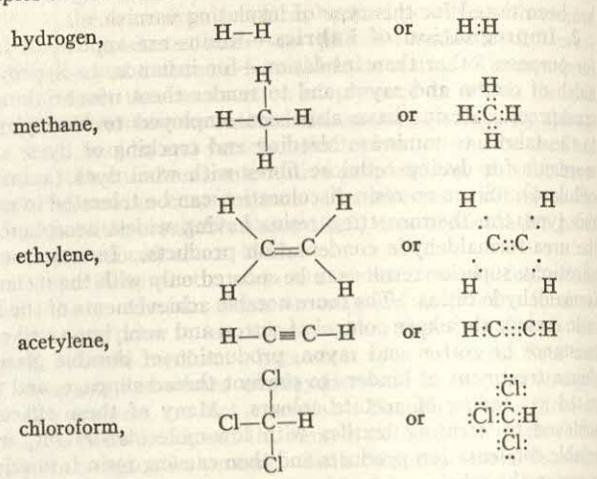
RESONANCE, a term used in physics and related fields originally denoting a prolongation or increase of sound because of sympathetic vibration of some body capable of moving in the proper period. An example is the oscillation induced in a violin or piano string of a given pitch when a musical note of the same pitch is sung or played nearby. For resonance in acoustical theory and experiment, *see* SOUND; in rooms and buildings, *see* ACOUSTICS OF BUILDINGS; as a theory of hearing, *see* HEARING; in violin construction, *see* VIOLIN FAMILY. The term has been extended by analogy to the familiar selective mechanical resonance of a springboard or bridge to certain frequencies of jumping or walking; and to the selective electrical resonance of a tuned radio circuit to the radio frequency transmitted by a single radio station. At the high frequencies used in microwaves and radar (*q.v.*), the tuned circuit is actually constructed most easily in the form of a small metal cavity resonator not unlike the cavity of an acoustical resonator such as an open-mouthed bottle.

See also references under "Resonance" in the Index.

(J. R. PT.)

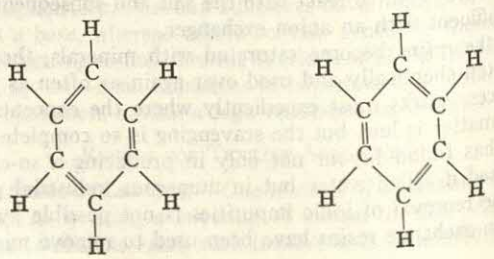
RESONANCE, THEORY OF, in chemistry, is an extension of the theory of valence (*q.v.*), which contributed greatly to the understanding of the structure of molecules and the structural interpretation of the chemical and physical properties of substances. The concept of resonance has been applied in chemistry in the elucidation of the nature of the covalent bond, of the partial ionic character of bonds and of other aspects of valence. Its most important chemical applications have been to aromatic molecules, molecules containing conjugated systems of double bonds, hydrocarbon free radicals, and other molecules to which no satisfactory single structure in terms of single bonds, double bonds and triple bonds can be assigned.

For many molecules it is possible to formulate valence-bond structures which are so reasonable and which account so satisfactorily for the properties of the substances that they are generally accepted and are used as the basis for chemical reasoning. Examples of such molecules are:



It is sometimes found, however, that a choice cannot be made between two or more conceivable structures which are expected to be about equally stable and of which no one accounts in a completely satisfactory way for the properties of the substance. The concept of quantum-mechanical resonance provided the solution to this problem; namely, the actual normal state of such a molecule can be described as corresponding not to any one of the alternative reasonable structures but rather to a combination of them, their individual contributions being determined by their nature and stability. The molecule is then said to resonate among the several valence-bond structures or to have a structure which is a resonance hybrid of these structures. The molecule is stabilized by this resonance, its energy being less than the energy which would be expected for any one of the structures among which it resonates. This stabilization is characteristic of the phenomenon of quantum-mechanical resonance, which was discovered by Werner Heisenberg in 1926 (*see* below). The physical and chemical properties of the substance and the configuration of the molecule are determined by the nature of the resonating structures; these properties are, however, not the properties averaged for the resonating structures but are instead the averaged properties as influenced also by the effects of resonance and in particular by the additional stability resulting from the resonance energy.

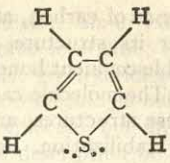
The aromatic substance benzene provides not only an illuminating but also the most important example of the application of the concept of the resonance of molecules among two or more valence-bond structures. The formulation of the structure of benzene as a six-membered ring of carbon atoms with attached hydrogen atoms was made by F. A. Kekulé in 1865. To make the structure compatible with the quadrivalence of carbon he introduced alternating single and double bonds in the ring, and later, in 1872, in order to account for the nonobservance of isomeric orthodisubstituted benzenes (differing in having a single bond or a double bond between the substituted carbon atoms), he introduced the idea of an oscillation between two structures:



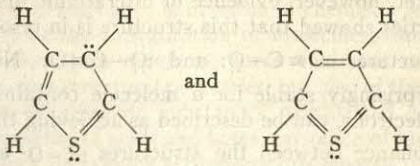
The Kekulé structure for benzene is unsatisfactory in that the substance does not show the properties of unsaturation to be expected for a molecule containing double bonds. After a period during which the centric structure of H. E. Armstrong and Adolf von Baeyer, the diagonal structure of A. Claus and the structure of J. Thiele based on his theory of partial valence were proposed, an important advance was made in the years following 1920 in the theory of intermediate stages proposed by F. Arndt and the theory of mesomerism developed by Sir Robert Robinson, C. K. Ingold and other English and U.S. chemists. The suggestion of these investigators, induced from the facts of chemistry, was that the true state of a molecule may be intermediate between those represented by several different valence-bond structures. Complete clarification of the structure of benzene was provided by Linus Pauling (1931) through application of the theory of resonance and consideration of the effect of resonance energy. According to the quantum-mechanical discussion of the structure of benzene, the normal state of this molecule can be represented as a hybrid of the two Kekulé structures  and three diagonal structures of the form (the *para* bond in these structures being a weak bond, almost equivalent to a free valence on each of the para carbon atoms) and other structures which make smaller contributions. The configuration of the molecule should be a suitable average of those configurations corresponding to the individual structures. Because of the resonance the six carbon-carbon bonds are equivalent, and because of the stereochemical properties of a double bond the molecule as a whole is planar; hence the benzene molecule is predicted to be a planar hexagonal molecule, in agreement with observations made by the electron diffraction, X-ray diffraction and spectroscopic methods. Moreover, each carbon-carbon bond should be intermediate in length between a single carbon-carbon bond and a double carbon-carbon bond, the lengths of which, in molecules represented by a single valence-bond structure, are 1.54 Å and 1.33 Å, respectively. The observed value in benzene, 1.39 Å, is compatible with this prediction. Moreover, the benzene molecule is predicted from the quantum-mechanical considerations to be stabilized by resonance energy to the extent of about 40 kg.cal. per mole, relative to the value expected for one of the Kekulé structures. The amount of resonance stabilization can be estimated experimentally by measurement of the heat of combustion or heat of hydrogenation of benzene and related substances. For example, the heat of hydrogenation of cyclohexene is 28.6 kg.cal. per mole; if each of the three double bonds in benzene were the same as the double bond in cyclohexene, the heat of hydrogenation of benzene would be 85.8 kg.cal. per mole, whereas in fact the observed value is 49.8, indicating that the benzene molecule is stabilized relative to a Kekulé structure by the amount of energy 36 kg.cal. per mole, in approximate agreement with the quantum-mechanical prediction. The characteristic chemical stability and non-reactivity shown by benzene, relative to simpler unsaturated substances, may be attributed to this stabilization by resonance. It is possible, moreover, by the detailed consideration of the resonating structures to explain in a reasonably satisfactory way the other striking chemical properties of benzene, such as the influence of one substituent in determining the position of attachment of further substituents to the ring.

The structures of polynuclear aromatic hydrocarbons are similar. Naphthalene, for example, can be described as resonating among the three structures  , with small contributions from other structures analogous to the *para*-bonded structures of benzene, and the resonance energy of naphthalene is found to be about 75 kg.cal. per mole.

The stabilization of the aromatic heterocyclic molecules such as thiophene results from resonance of the most important structure



with structures such as

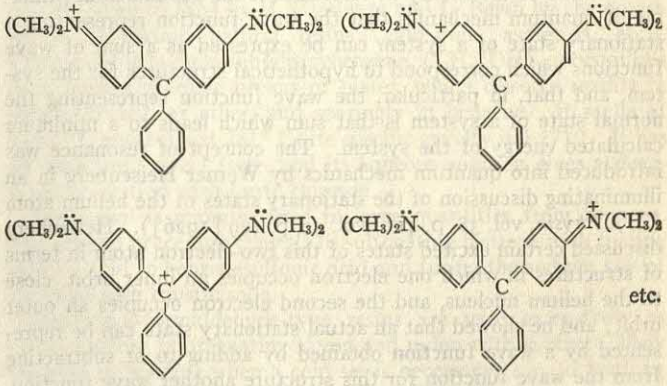


The resonance energy for thiophene is about 30 kg.cal. per mole.

The characteristic properties of substances which contain conjugated systems of double bonds can be readily accounted for by the theory of resonance. A molecule such as biphenyl,  , is stabilized not only by Kekulé resonance but also by the resonance energy of conjugation, resulting from the contributions of the somewhat less stable structures of type  .

For biphenyl, phenyl ethylene and butadiene the resonance energy of conjugation is about five kg.cal. per mole. There are two stereochemical effects of this conjugation: the carbon-carbon distance for the single bond involved in the conjugated system is decreased from the single-bond value, 1.54 Å, to about 1.48 Å, as the result of the contribution of the conjugated structures with a double bond in this position; and the double-bond character of this bond also finds expression in the tendency to hold the adjacent bonds in the planar configuration. These molecules are observed to be planar or nearly planar, except when planarity is prevented by the arrangement of valence bonds or by steric effects, in which case the properties of the substance show that there is interference with the conjugation.

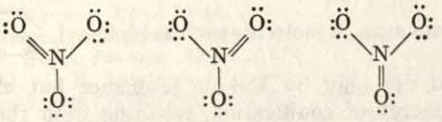
The phenomenon of resonance can be invoked in the discussion of the colour of dyes and other organic substances. The normal state of the cation of malachite green, for example, involves resonance among all structures of the sort shown below, in which the positive charge is located on different atoms within the molecule:



The excited states of the molecule are similar resonating states involving these structures. The absorption of light by the molecule, with its transition from the normal state to an excited state, occurs with great ease; the quantum-mechanical molecule can be compared with a classical oscillator in which a positive charge is resonating through a large amplitude, from one nitrogen atom across to the other, and from this comparison it can be predicted that the molecule should show intense absorption of light of suitable wave lengths.

Resonance also provides an explanation of the properties of many inorganic substances. For example, the carbon-monoxide molecule is a far more stable molecule than would be expected

from the apparent bivalence of carbon, and there was formerly discussion as to whether its structure should be written as :C=Ö:, containing a double covalent bond, or as :C≡O:, similar to the nitrogen molecule. The molecule can be assigned a hybrid structure based upon these structures, and its stability can be attributed to resonance stabilization. For carbon dioxide the structure :Ö=C=Ö: was for many years accepted without question; later, however, evidence of interatomic distances and other properties showed that this structure is in resonance with the two structures :O≡C−Ö: and :Ö−C≡O: Nitric oxide, which is surprisingly stable for a molecule containing an odd number of electrons, can be described as achieving this stability through resonance between the structures :Ṅ=Ö: and :N=O:, and may be said to have a double bond plus a three-electron bond between its two atoms. The nitrate ion, NO_3^-, resonates among the three structures



making each of the nitrogen-oxygen bonds a hybrid between a single bond and a double bond.

The general rules regarding the resonance of a molecule among alternative valence-bond structures are the following: Equivalent structures contribute equally to the normal state of the resonating molecule. The more stable structures in general make larger contributions to the normal state, and less stable structures make smaller contributions. The electronic state of the resonating molecule applies to a definite configuration of the atomic nuclei; accordingly the energy values of the individual structures to be considered in connection with the foregoing statements are those calculated for the nuclear configuration of the actual state of the molecule and not for nuclear configurations which would be the most stable for the individual structures. The strain involved in this change in configuration in some cases makes structures unimportant which otherwise might be important. All of the structures which contribute to a resonance hybrid structure must have the same number of unpaired electrons; significant resonance does not occur, for example, between a structure with no unpaired electrons (singlet state) and a structure with two unpaired electrons (triplet state).

The basis of the theory of resonance is the fundamental principle of quantum mechanics that the wave function representing a stationary state of a system can be expressed as a sum of wave functions which correspond to hypothetical structures for the system, and that, in particular, the wave function representing the normal state of a system is that sum which leads to a minimum calculated energy of the system. The concept of resonance was introduced into quantum mechanics by Werner Heisenberg in an illuminating discussion of the stationary states of the helium atom (*Z. f. Physik*, vol. 38, p. 411; vol. 39, p. 499 [1926]). Heisenberg discussed certain excited states of this two-electron atom in terms of structures in which one electron occupies an inner orbit, close to the helium nucleus, and the second electron occupies an outer orbit; and he showed that an actual stationary state can be represented by a wave function obtained by adding to or subtracting from the wave function for this structure another wave function, representing the structure in which the second electron occupies the inner orbit and the first electron the outer orbit. On the basis of analogy with the classical system of resonating coupled harmonic oscillators, he assigned the name quantum-mechanical resonance to this concept (*see* ATOM; QUANTUM MECHANICS; SPECTROSCOPY).

The special usefulness of the harmonic oscillator in the interpretation of quantum mechanics results from the fact that when this system is treated by the methods of classical mechanics and the old quantum theory, with the number ½ added to the integral values of the quantum number, many of the calculated properties of the system are the same as those given by quantum mechanics. The simplest system illustrating resonance consists of two equivalent harmonic oscillators with a weak Hooke's law coupling between them. The potential energy for this system may be represented by the expression $2\pi^2 m\nu_o^2 x_1^2 + 2\pi^2 m\nu_o^2 x_2^2 + 4\pi^2 m\lambda x_1 x_2$, and the kinetic energy by $\frac{1}{2}mx_1^2 + \frac{1}{2}mx_2^2$, where m is the mass of each oscillator, x_1 and x_2 are the displacements of the oscillators from their positions of rest, ν_o is the characteristic frequency of oscillation of each oscillator when there is no coupling ($\lambda = 0$), and λ is a parameter determining the strength of the coupling. The classical equations of motion for this system can be solved in terms of the normal co-ordinates $\xi = \frac{1}{\sqrt{2}}(x_1 + x_2)$ and $\eta = \frac{1}{\sqrt{2}}(x_1 - x_2)$. Each of these normal co-ordinates varies harmonically with the time, t, the integrated equations of motion being $\xi = \xi_o \cos(2\pi\sqrt{\nu_o^2 + \lambda}\,t + \delta_\xi)$ and $\eta = \eta_o \cos(2\pi\sqrt{\nu_o^2 - \lambda}\,t + \delta_\eta)$ in which ξ_o, η_o, δ_ξ and δ_η are the constants of integration. It is seen that the characteristic frequencies for ξ and η, $\sqrt{\nu_o^2 + \lambda}$ and $\sqrt{\nu_o^2 - \lambda}$ respectively, differ from ν_o. The co-ordinates x_1 and x_2 are then given by the equations

$$x_1 = \frac{\xi_o}{\sqrt{2}}\cos(2\pi\sqrt{\nu_o^2 + \lambda}\,t + \delta_\xi) + \frac{\eta_o}{\sqrt{2}}\cos(2\pi\sqrt{\nu_o^2 - \lambda}\,t + \delta_\eta)$$

and

$$x_2 = \frac{\xi_o}{\sqrt{2}}\cos(2\pi\sqrt{\nu_o^2 + \lambda}\,t + \delta_\xi) - \frac{\eta_o}{\sqrt{2}}\cos(2\pi\sqrt{\nu_o^2 - \lambda}\,t + \delta_\eta).$$

If η_o is zero, the two oscillators carry out, exactly together in phase, a simple harmonic motion with amplitude $\frac{\xi_o}{\sqrt{2}}$ and frequency $\sqrt{\nu_o^2 + \lambda}$; and if ξ_o is zero, they carry out, with phase difference π, a similar harmonic motion with amplitude $\frac{\eta_o}{\sqrt{2}}$ and frequency $\sqrt{\nu_o^2 - \lambda}$; but if neither η_o nor ξ_o vanishes, each of the oscillators vibrates in a complex way, the amplitude changing slowly from $\frac{\xi_o + \eta_o}{\sqrt{2}}$ to $\frac{|\xi_o - \eta_o|}{\sqrt{2}}$. This is the phenomenon described as classical resonance.

The rules of the old quantum theory with zero-point energy lead to the value $(n_\xi + \frac{1}{2})\,h\sqrt{\nu_o^2 + \lambda} + (n_\eta + \frac{1}{2})\,h\sqrt{\nu_o^2 - \lambda}$ for the energy of this system, and to the equations

$$\xi_o = \{(n_\xi + \tfrac{1}{2})h/2\pi^2 m\sqrt{\nu_o^2 + \lambda}\}^{\frac{1}{2}}$$

and $$\eta_o = \{(n_\eta + \tfrac{1}{2})h/2\pi^2 m\sqrt{\nu_o^2 - \lambda}\}^{\frac{1}{2}}$$

for the amplitudes. Each of the quantum numbers n_ξ and n_η can assume the values 0, 1, 2, ... Since neither ξ_o nor η_o can vanish, even when the quantum number is zero, the oscillators show the phenomenon of classical resonance in every quantized state.

The stationary states of a harmonic oscillator in quantum mechanics are described by wave functions $\psi_o(x)$, $\psi_1(x)$, $\psi_2(x)$, ..., $\psi_n(x)$, ..., corresponding to the energy values $(n + \frac{1}{2})h\nu_o$ with integral values for the quantum number n. The wave functions $\psi_n(x)$ are the successive Hermite orthogonal functions. The system of two equivalent coupled harmonic oscillators (with the same frequency) can be treated rigorously by use of the co-ordinates ξ and η, and the correct wave functions for the system are $\psi_{n_\xi}(\xi)\psi_{n_\eta}(\eta)$, the energy values being the same as for the old quantum theory, as given above. In this discussion of the system there is no need to mention resonance. However, the system may also be treated by a perturbation method, based on the wave functions $\psi_{n'}(x_1)\psi_{n''}(x_2)$ for the unperturbed system, with no coupling between the oscillators. For the normal state of the system, with $n' = n'' = 0$, there is only one wave function. There are, however, two independent wave functions, $\psi_o(x_1)\psi_1(x_2)$ and $\psi_1(x_1)\psi_o(x_2)$, for the next energy level; these functions correspond to states in which one oscillator has small energy, $\frac{1}{2}h\nu_o$, and the other has larger energy, $3/2h\nu_o$. It is found on treating the system of coupled oscillators that these functions are not satisfactory approximations to the correct wave func-

tions representing the two slightly different energy levels of the system, but that their normalized sum and difference, $\frac{1}{\sqrt{2}}[\psi_0(x_1)\psi_1(x_2) + \psi_1(x_1)\psi_0(x_2)]$ and $\frac{1}{\sqrt{2}}[\psi_0(x_1)\psi_1(x_2) - \psi_1(x_1)\psi_0(x_2)]$, are satisfactory; the first wave function, symmetrical in the two coordinates x_1 and x_2, represents the more stable of the two states, and the second, antisymmetrical in x_1 and x_2 (changing sign when x_1 and x_2 are interchanged), represents the less stable state. Each of these states is a hybrid of the two structures represented by $\psi_0(x_1)\psi_1(x_2)$ and $\psi_1(x_1)\psi_0(x_2)$, and, from analogy with the classical system, it has become customary to describe these hybrid states as resonance hybrids. This description is applied also to other quantum-mechanical systems which are conveniently discussed by a similar perturbation method, even though there is no close classical analogue for them.

The arbitrary nature of quantum-mechanical resonance is evident from the foregoing paragraphs. The system of coupled harmonic oscillators can be treated rigorously without mentioning resonance. It is for convenience, resulting from knowledge of the unperturbed wave functions, that these functions are used in the perturbation treatment. Quantum-mechanical resonance is not a property of a system, but of a system in relation to structures which are assumed as the basis for its discussion. In chemistry the theory of resonance is used primarily as an aid in discussing the structure and properties of complex molecules in terms of simple molecules. Simple structures similar to those which have been assigned to simple molecules are assumed as the basis for the discussion of complex molecules; and often when no one of the simple structures is satisfactory, a resonance hybrid can be formulated which represents the complex molecule in a satisfying and useful way.

The arbitrariness mentioned above is not characteristic of the theory of resonance in chemistry, but is shared by it with other branches of structural theory. It is recognized now that the structures of molecules may be correctly described by the quantum-mechanical wave functions pertaining to their normal states, and that the structural formulas assigned by chemists are symbols for the wave functions. For nearly a century chemists have written the simple valence-bond formulas H — H for molecular hydrogen, Cl — Cl for molecular chlorine and H — Cl for hydrogen chloride. The dash in the formulas H — H and Cl — Cl is a symbol for wave functions describing the normal states of these diatomic molecules formed of identical atoms. The normal state of the hydrogen chloride molecule is, of course, correctly described by its wave function, and this wave function is not rigorously related to the wave functions of the hydrogen molecule and the chlorine molecule. Nevertheless, chemists have found it convenient to assign the structural formula H — Cl to the molecule with use of a dash like that used in the formulas H — H and Cl — Cl, and to describe the hydrogen chloride molecule, like the hydrogen molecule and the chlorine molecule, as involving a single valence bond. Thus the valence-bond structural theory, which has been of great value in the development of chemistry, is an arbitrary approximate representation of the wave functions that alone correctly represent the molecules. It is conceivable that a system of symbols much different from the valence-bond dashes could be developed that would correspond just as well to the wave functions, but in fact a satisfactory alternative system of this sort has not been discovered, and chemists continue to use the valence-bond theory.

The theory of resonance in chemistry has been subjected to criticism because of its arbitrariness. The critics may not have recognized that, as mentioned above, the same criticism applies to the whole of structural theory. A structural formula for a nonresonating molecule such as ethane is a rough description of the wave function in terms of wave functions involving first a hydrogen nucleus, a carbon nucleus and a pair of electrons, and second two carbon nuclei (each with its inner shell of K electrons) and a pair of electrons. In the same way the structural formula for the resonating molecule benzene is a rough description of the wave function of benzene as a sum of valence-bond wave functions similar to the one assigned to ethane; the two Kekulé structures and other structures that are hybridized in the resonance representation of the benzene molecule do not correspond separately to states of the benzene molecule, but are symbols that, taken together, provide a rough description of the wave function of the molecule in its normal state.

The theory of resonance is of value in chemistry in the discussion not only of the configuration of molecules, interatomic distances, electric dipole moments, force constants of bonds and similar molecular-structural properties, but also of thermodynamic stability (as of aromatic substances, conjugated systems, free radicals), strengths of acids and bases, existence of tautomers (*see* TAUTOMERISM), and chemical properties in general.

See L. Pauling, *The Nature of the Chemical Bond and the Structure of Molecules and Crystals,* 3rd ed. (1959); G. W. Wheland, *Resonance in Organic Chemistry* (1955). (L. C. P.)

RESONANCE ENERGIES, also resonance potentials, are general expressions denoting energy differences between the stationary states of atoms, molecules, and atomic nuclei. The term resonance was first applied because of the apparent analogy between acoustical or electrical resonance (*q.v.*) and the selective absorption or emission of certain light frequencies by these microscopic systems. Since the energy absorbed is proportional to the frequency, the microscopic system can only absorb or emit particular selected amounts of energy, which carry it from one stationary state of internal energy (or potential) to another; this holds whether the energy is the radiant energy in a particle of radiation or the kinetic energy of motion in a colliding particle of matter that hits the microscopic system (*see* ATOMIC AND MOLECULAR BEAMS; ELECTRON PARAMAGNETIC RESONANCE).

In structural chemistry, however, the "resonance energy" of a molecule has quite a different meaning. It refers to the deviation of the energy of formation of a molecule from a hypothetical ideal energy which is conceived as the sum of the energies of its parts. Here the term resonance is supposed to be drawn from a branch of quantum theory and is only distantly related to acoustical or mechanical resonance (*see* RESONANCE, THEORY OF). (J. R. PT.)

RESORCINOL (also called RESORCIN) is an organic chemical used in the manufacture of adhesive resins, plastics, dyes (*e.g.,* fluorescein, *q.v.*), photographic developers, explosives, cosmetics, and pharmaceuticals, and as an intermediate in the synthesis of many other organic compounds. It is used medicinally as a dehydrant, antiseptic, antiferment, and bactericide. Resorcinol was first obtained in 1864 by H. Hlasiwetz and L. Barth by the potash fusion of certain natural resins (galbanum, asafetida, etc.). Chemically it is meta-dihydroxybenzene, $C_6H_4(OH)_2$, crystallizes in colourless rhombic prisms or plates, which dissolve readily in water, alcohol, or ether, and sparingly in benzene. It melts at 110.7° C and boils at 281° C; its specific gravity is 1.2710. It has an unpleasant sweet taste, and its aqueous solution gives a deep-violet coloration with ferric chloride.

Resorcinol is manufactured in large quantities from benzene. The general procedure consists in sulfonating benzene with fuming sulfuric acid to benzenesulfonic acid and fusing the sodium salt of this acid with caustic soda.

Resorcinol-formaldehyde-type resins are used extensively as pre-dip before impregnating rayon and nylon with rubber. They are used in bonding when a cold set is necessary; *e.g.,* in bonding wooden members that are too thick to be heated.

RESPIGHI, OTTORINO (1879–1936), Italian composer, was born at Bologna on July 9, 1879, and studied at the Liceo of Bologna and later with Rimski-Korsakov in St. Petersburg and with Max Bruch in Berlin. From his foreign masters Respighi acquired a command of orchestral colour and an interest in orchestral composition. In 1913 he was appointed professor of composition at the Sta. Cecilia Academy in Rome. He was director

there in 1924, but resigned in 1926, retaining a class in advanced composition. He had a talent for colourful descriptive music of a lyrical character illustrated in the series of suites, *Le Fontane di Roma* (1917), *I Pini di Roma* (1924), *Vetrate di chiesa* (1927), and *Trittico botticelliano* (1927), the last for chamber orchestra. He was also drawn to old Italian music, which he arranged with skill and taste in two sets of *Antiche danze e arie per liuto*. One of his most popular scores was his arrangement of pieces by Rossini, *La Boutique fantasque*, produced by Diaghilev's Russian Ballet in London (1919).

As a composer of opera Respighi had less success outside his own country. His best works for the theatre were *Belfagor*, a comic opera produced at Milan in 1923, and *La Fiamma* (Rome, 1934), which transfers the gloomy Norwegian tragedy of H. Wiers Jenssen (known to English-speaking audiences in John Masefield's version as *The Witch*) to Byzantine Ravenna with brilliant effect. In a different, more subdued vein are the "mystery," *Maria Egiziaca* (1932), and *Lucrezia* (completed by his wife E. Respighi, 1937), the latter showing Respighi's interest in the dramatic recitative of Claudio Monteverdi, of whose *Orfeo* he made a free transcription for La Scala, Milan, in 1935. Respighi died in Rome on April 18, 1936. His wife and pupil, Elsa Olivieri-Sangiacomo Respighi, born in Rome on March 24, 1894, was a singer and composer of operas, choral and symphonic works, and songs.

See E. O. Respighi, *Ottorino Respighi* (1954; Eng. trans. 1962); R. de Rensis, *Ottorino Respighi* (1935). (Dy. H.)

RESPIRATION is the transfer of gases between living organisms and their environment. It goes hand in hand with metabolism (*q.v.*), a process akin to combustion, whereby foodstuffs are oxidized, just as fuel is, with the release of energy for the needs of the organism. The gaseous exchange for man is the same basically as that for a fire, oxygen being taken out of the environment and carbon dioxide released to it. Yet biological oxidations go on at temperatures hundreds of degrees lower than those of a fire, owing to the presence of enzymes (chemical catalysts) in the tissues.

This article explains the principles of respiration generally, describes various respiratory mechanisms in animals, and then considers in detail the physiology of respiration in man. For closely related information *see* Respiratory System, Anatomy of; Respiratory System, Diseases of; and references under "Respiration" in the Index. For the respiratory process in plants *see* Plants and Plant Science: *Plant Physiology: Respiration*.

Diffusion of Gases in Respiration.—Virtually every living animal, be it amoeba or whale, receives its oxygen and gets rid of the carbon dioxide produced by means of diffusion (*q.v.*). This process refers to the net movement of molecules, by virtue of their constant random activity, from regions of higher toward those of lower concentration. Transfer of substances by diffusion, however, is characteristically slow except over extremely short distances. This is illustrated by Fick's law of diffusion, which in simplified form is:

$$\frac{Q}{t} = \frac{DA(C_1 - C_2)}{h}$$

where $\frac{Q}{t}$ = quantity of substance diffusing per unit time; D is the diffusion coefficient, a constant depending on the nature of the substance diffusing, on the material it is in, and on the temperature; A = the area of the surface; $(C_1 - C_2)$ = the concentration difference across the material; and h = the thickness of the substance across which diffusion is occurring. Thus, the rate of diffusion is directly proportional to the surface area and to the concentration difference, and inversely proportional to the thickness.

Respiratory Adaptations in Evolution.—Sufficient gas exchange for an amoeba (diameter 0.5 mm., or $\frac{1}{50}$ in.) can be provided by diffusion across the surface membrane. With increasing size of spherical organisms, the mass of metabolizing tissue increases more rapidly than the surface area, a point being reached at a diameter of about 1 mm. ($\frac{1}{25}$ in.) when the diffusing area is not large enough to meet the need. As a result, there has evolved in the majority of metazoa, or multicellular organisms, some kind of specialized respiratory system, and with it a circulatory system. These are well-suited to their function by virtue of the thin walls and large surface areas of the layers separating the circulating fluid (usually blood) from the external environment (water or air) on the one hand and from the active cells on the other.

Four chief means for respiration have appeared:

1. The first and simplest is by way of the surface membrane, mentioned above in the case of the protozoan amoeba. Diffusion across the surface layer also suffices in certain of the more primitive metazoa, both aquatic and terrestrial. Convection often aids diffusion by movement of sea water, as in sponges, and by the constant stirring of blood that occurs in animals with circulatory systems.

In some cases the skin shares the burden of respiration with specialized organs. Thus, in cold surroundings, eels and frogs can obtain most of their oxygen through the surface of the body but, when the temperature is higher, need their gills and lungs, respectively. In mammals, including man, however, the amount of oxygen received through the skin is negligible (usually less than 1%).

2. Gills represent a second chief means for respiration. Most gills are motile and are located, usually inside the body, in a moving current of water, the gas exchange being enhanced by the "countercurrent" principle, whereby the blood flows in a direction opposite to that of the water. (Purification of the blood would be much less complete were the two to go in the same direction.)

3. Third are lungs, usually aerial, though sometimes water-filled. One of the simplest forms is seen in the pulmonate land snails, in which the lung consists of a simple air sac, called a diffusion lung because there is no active ventilation.

Ventilatory lungs are those in which there is a bellows function, air being moved in and out by mechanical movements. There are positive pressure lungs, in which air is pushed into the lung while the nostrils are closed, as in frogs, contractions of abdominal muscles causing expiration. Negative pressure lungs are those in which air is pulled in by expansion of a bony thoracic cage, as in man and other mammals.

With increasing demands for energy the surface area available for diffusion becomes increased by subdivision of the lung into progressively smaller and smaller air sacs, called alveoli. Thus, the lung of an amphibian such as a frog contains a few hundred alveoli, whereas that of a man or a large animal contains hundreds of millions.

Greater efficiency per unit of diffusing surface exists in birds through improved ventilation. This is achieved by means of two unique anatomical features—a tubular diffusing system (in contrast to the dead-end alveoli of mammals) and a group of air sacs located beyond the lung. An idea of this arrangement is given in fig. 1. Airways called parabronchi lead off each main bronchus and continue through the lung into one of several pairs of air sacs, located in the neck, thorax, abdomen, and even inside the long bones. Each air sac is also connected to the bronchus by way of a mesobronchus. Diffusion of gases takes place in air capillaries, which, connecting adjacent parabronchi, are surrounded by a rich network of minute blood vessels.

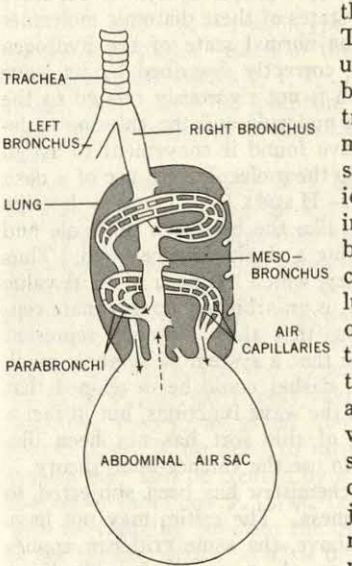

FIG. 1.—RESPIRATORY SYSTEM IN BIRDS SHOWING RIGHT LUNG AND ONE OF THE SEVERAL AIR SACS CONNECTED TO IT

Solid arrows indicate probable pathway of air flow during inspiration; dashed arrow, probable pathway during expiration

By means of rapid gas analyzers for oxygen and carbon dioxide, R. H. Shepard showed that in the chicken, inspired air passes almost solely through the parabronchial diffusing system and on

into the air sacs. Air leaves the latter during expiration by way of the mesobronchus without passing back over the respiratory surfaces, as suggested by earlier investigators. The path is therefore mouth to lung to air sacs to mouth, a process requiring a valvelike action despite the absence of anatomical valves.

4. The fourth type of respiratory mechanism consists of the tracheae of insects—narrow, air-filled, branching tubes that open to the outside of the body by way of spiracles. A circulating fluid such as blood is of minor importance for breathing in these organisms, the air being piped directly to the tissues. Tracheal respiration has served the insects well, but because gases diffuse slowly along a narrow tube, it has been a factor in limiting their size. *See* INSECT: *Structure and Function: Respiration.*

VENTILATION OF THE LUNGS IN MAN

Distribution of Gas and Blood to the Lungs.—Incoming air is filtered by hairs in the nose, which remove larger dust particles, and is warmed and moistened as it passes down through the pharynx, becoming saturated with water vapour by the time it reaches the trachea (windpipe). The trachea branches into the right and left main stem bronchi, the branching continuing with the secondary bronchi, the bronchioles, and finally the respiratory bronchioles which lead into the primary lung lobule, the functional unit of the lung. The incoming air is thus distributed to the 300,000,000 or so alveoli, where exchange of oxygen and carbon dioxide between air and blood takes place. Each alveolus, 0.1 to 0.3 mm. ($\frac{1}{250}$ to $\frac{3}{250}$ in.) in diameter, consists essentially of a bundle of capillary blood vessels suspended in air. Most of its surface is covered by these vessels, the total length of which is about 2,400 km. (1,500 mi.), spread out in order to provide 65 to 80 sq.m. (700 to 860 sq.ft.) of diffusing surface, only about 0.36 to 2.5 microns ($\frac{14}{1,000,000}$ to $\frac{1}{10,000}$ in.) in thickness in an adult man. The blood in each capillary is renewed each 0.9 second at rest and each 0.3 second or less during exercise. The total blood flow through the lung is about 5 l. (5¼ qt.) per minute at rest and up to 20 to 27 l. (21 to 28½ qt.) during severe exercise. About 4 l. (4¼ qt.) of air reach the alveoli each minute during rest and as much as 100 l. (106 qt.) during exercise.

Diffusion of Oxygen and Carbon Dioxide Across the Lung.—In the closed swim bladders of physoclist fishes, a special gas gland in conjunction with a network of blood vessels is able to secrete oxygen at concentrations up to 87% and at several atmospheres' pressure. Partly because of this fact, C. Bohr and later John Scott Haldane postulated that oxygen was secreted by the lungs of human beings under certain conditions. Repeated experiments, however, have indicated that the oxygen concentration is always higher in the air of the lung than in the blood (the reverse being true for the outgoing carbon dioxide), a fact consistent with diffusion and not with secretion.

The concentration of a gas at a given temperature is expressed in terms of partial pressure, in millimetres of mercury (as indicated under *Dalton's Law of Partial Pressures and Its Application to Respiration,* below). During rest, the partial pressure of oxygen in the air of the lung is about 8 to 10 mm. higher than the average partial pressure of the blood in the capillaries of the lung. This diffusion gradient increases as the oxygen consumption goes up, reaching as high as 50 mm. during severe exercise. Even with so large a mean gradient, however, the partial pressure of oxygen in the blood leaving the lung is normally only a few millimetres less than that of the air in the lung. This is because the average partial pressure of oxygen in the pulmonary capillary lies somewhere between that of venous and arterial blood.

It is customary to speak of the diffusing capacity ($D_{L_{O_2}}$) of the lung as a whole, defined as the number of millilitres of O_2 diffusing each minute, as a result of a 1-mm. diffusion gradient for O_2. At rest, $D_{L_{O_2}}$ = approximately 25 (*i.e.,* 250 ml. of O_2 diffuse across the lung per minute when the diffusion gradient equals 10 mm). During exercise, the $D_{L_{O_2}}$ may rise to as high as 80, due presumably to enlargement of existing lung capillaries and the opening up of new ones. The $D_{L_{CO_2}}$ is about 20 times as great as the $D_{L_{O_2}}$ because CO_2 is more soluble in tissues and blood than O_2 and therefore diffuses more readily.

Mechanics of Respiration.—Air is moved in and out of the lungs as the result of changes in the volume of the thoracic cavity, the lungs playing an entirely passive role and neither expanding nor contracting by themselves. Thus, the energy required for

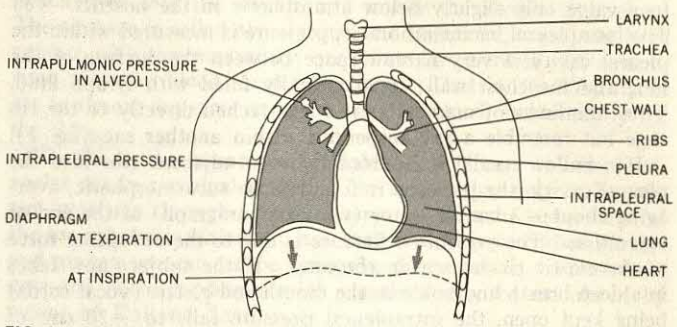

FIG. 2.—DIAGRAM OF CHEST SHOWING HOW LUNG EXPANDS AND AIR IS TAKEN IN BY DESCENT OF DIAPHRAGM

Distance of descent of the diaphragm, here exaggerated for illustrative purposes, is about 1.25 cm. (½ in.). Inspiration is aided by expansion (not shown) of chest wall. Intrapleural pressure and intrapulmonic pressure in alveoli are explained in text

breathing comes from muscles located entirely outside the lungs. These are (1) the powerful muscle known as the diaphragm, on the bottom of the cavity, and (2) numerous muscles of the thoracic and abdominal walls. The lungs are elastic sacs constantly tending to collapse. Suspended within the barrellike thoracic cage, they are prevented from doing so by the arched structure of the ribs at the sides and by the contractions of the diaphragm below.

Approximately 500 ml. (about a pint) of air is taken in with each breath as a result of two mechanical events:

1. Impulses descending the phrenic nerve, which goes solely to the diaphragm, cause the latter to contract and move downward. Since the descent averages 1.25 cm. (½ in.) and the surface area equals 250 sq.cm., about 300 ml. of air (60% of the total) is taken in by this means.

2. Contractions of several sets of muscles that originate at the spine and run forward and downward to the ribs elevate the latter during inspiration, causing an increase in the internal volume of the chest. About 200 ml. of air is taken in by this means. The expansion is due to the arrangement of the ribs, which are semicircular strips of bone, hinged posteriorly at the spine, the plane formed by their circumference inclined downward and outward. Each rib may be compared to the handle of a pail. Raising the handle increases its horizontal distance from the pail. Similarly, raising the ribs increases the antero-posterior diameter of the chest. Because the ribs are hinged obliquely to the spine, the lateral dimension of the chest is also increased, the enlargement being accommodated by the flexible rib cartilages which connect the forward ends of the ribs to the sternum (breastbone).

At the end of inspiration, with normal, quiet breathing (eupnea), the nervous activity originating in the respiratory centres of the brain ceases, and the chest collapses as a result of the elastic recoil of the lungs. However, during hyperpnea—the rapid, deep breathing seen in exercise or disease—expiration becomes active, involving various thoracic muscles, which pull the ribs down, and abdominal muscles, which push the diaphragm upward to facilitate the expulsion of air.

The mechanical factors involved in respiration have been evaluated by measuring the hydrostatic pressures in certain parts of the respiratory system, together with the volume of air breathed in or out and the rate of air flow. As a result, quantitative information is available regarding the elastic properties of the lungs, the resistance to air flow within the airways, and the mechanical work of breathing.

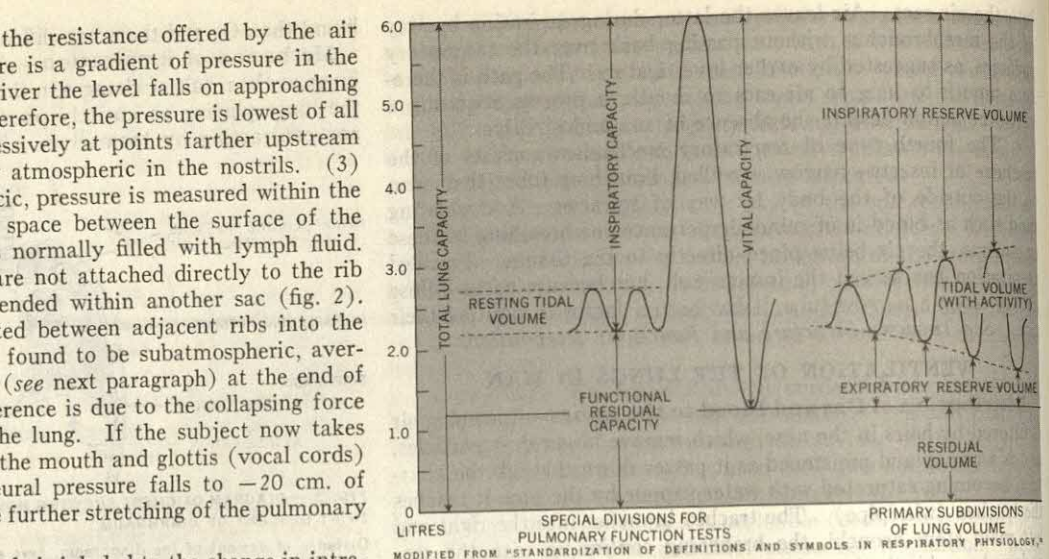
The significant hydrostatic pressures are: (1) Atmospheric (barometric) pressure, the reference level to which other pressures are compared, including that of the surrounding air. (2) Intrapulmonic pressure, defined as the pressure inside one of the airways of the respiratory tree. The location must be specified,

because as a consequence of the resistance offered by the air passages to the flow of air there is a gradient of pressure in the direction of flow, just as in a river the level falls on approaching the sea. During inspiration, therefore, the pressure is lowest of all in the alveoli, and rises progressively at points farther upstream to a value only slightly below atmospheric in the nostrils. (3) The intrapleural, or intrathoracic, pressure is measured within the pleural cavity, a very narrow space between the surface of the lung and the chest wall; it is normally filled with lymph fluid. Thus, the lungs of mammals are not attached directly to the rib cage but resemble a sac suspended within another sac (fig. 2).

If a hollow needle is inserted between adjacent ribs into the pleural cavity, the pressure is found to be subatmospheric, averaging about −3 cm. of water (*see* next paragraph) at the end of expiration. The pressure difference is due to the collapsing force of the elastic tissues within the lung. If the subject now takes in a deep breath and holds it, the mouth and glottis (vocal cords) being kept open, the intrapleural pressure falls to −20 cm. of water or even lower, due to the further stretching of the pulmonary elastic tissues.

The relation of the volume of air inhaled to the change in intrapleural pressure is called the "compliance" or ease of expansion of the lung, and is expressed as litres of change in lung volume per change in pressure in centimetres of water. Values for normal subjects average 0.225 l./cm. (*i.e.*, after inhalation of 0.225 l. of air the intrapleural pressure falls 1 cm. H_2O). The compliance decreases in illnesses in which fibrous tissue forms within the lung.

When a given volume of air is flowing, the resulting pressure drop is proportional chiefly to the airway resistance, R (= pressure/flow, as in Ohm's Law for electricity), and slightly to the resistance of the tissue to deformation (viscosity). Expressed in centimetres of water per litre per second, R averages 2 cm./l./sec. for normal subjects. (This means that if air is being exhaled at the rate of one litre per second, the pressure in the alveoli will be 2 cm. H_2O higher than atmospheric.)



MODIFIED FROM "STANDARDIZATION OF DEFINITIONS AND SYMBOLS IN RESPIRATORY PHYSIOLOGY," FEDERATION PROCEEDINGS, VOL. 9

FIG. 4.—LUNG VOLUMES AS THEY APPEAR ON THE TRACING OF A SPIROMETER (VOLUME MEASURING DEVICE)

The vital capacity is the volume of a largest single breath; the tidal volume that of a normal breath. Inspiratory capacity is the volume that can be inhaled at the end of normal expiration; expiratory reserve, the volume exhaled at the end of normal expiration; and residual volume, the air remaining even after a forced expiration. The latter volume cannot be measured by a spirometer, but by an indirect method involving collection of an inert gas such as nitrogen

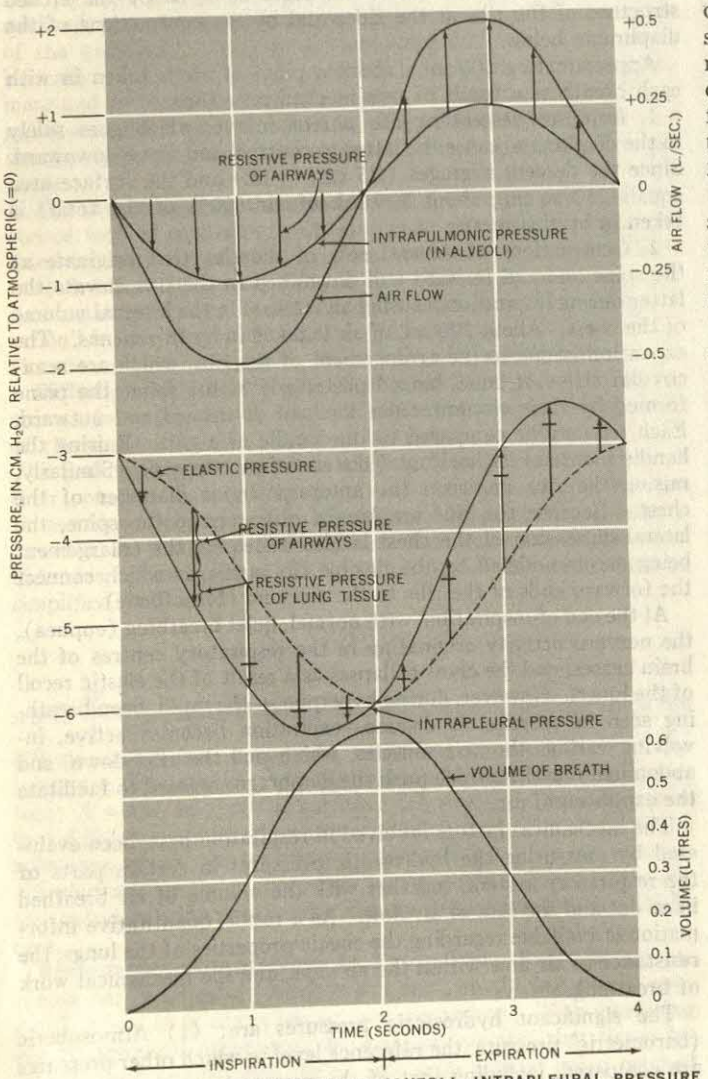


FIG. 3.—INTRAPULMONIC PRESSURE IN ALVEOLI, INTRAPLEURAL PRESSURE AND VOLUME OF AIR BREATHED, PLOTTED DURING ONE RESPIRATORY CYCLE. NUMERICAL VALUES SHOWN ARE FOR A NORMAL SUBJECT

The dynamic events occurring during one respiratory cycle are shown in fig. 3. The highest air flow during inspiration and expiration = 0.5 l./sec. in this example. As predicted by the equation relating pressure to flow (assuming R = 2 cm./l./sec., as above), intra-alveolar pressure reaches peak values of ±1 cm. of water.

The changes in intra-alveolar pressure due to resistance to the flow of air are transmitted through the lung and hence influence intrapleural pressure in the same direction. Thus, the curve for intrapleural pressure is made up of two components, elastic and resistive.

During heavy breathing accompanying exercise, the rapid flow of air causes greater swings in intra-alveolar and intrapleural pressures. The mechanical work required to inflate and deflate the lung, equal to change in intrapleural pressure times volume of air breathed, is therefore increased. It is also increased, even to the point of exhaustion, in patients with asthma, due to the wide swings in pressure needed to overcome the increased resistance to air flow which accompanies this condition.

Lung Volumes.—The lung of a man who weighs 80 kg. (175 lb.) holds about 6 l. (6⅓ qt.) of gas; this is called the total lung capacity. This is subdivided into components as indicated in fig. 4. Measurement of vital capacity and of the other lung volumes is an important diagnostic procedure in pulmonary disease.

Dalton's Law of Partial Pressures and Its Application to Respiration.—Certain physical properties of gases in general must be considered in relation to gas exchange in the body. Whether a gas such as oxygen will combine with the hemoglobin of the blood and will diffuse from air to blood and thence to the tissues depends on the molecular concentration of the oxygen.

Chemical analysis of atmospheric air has shown that it contains the following percentages of gases, expressed as volumes of dry gas per 100 volumes of dry air: O_2, 20.95%; CO_2, 0.03%; N_2, 78.08%; argon, 0.93%; and traces of each of seven other gases. These percentages are virtually constant, not only all over the surface of the earth but up to altitudes of approximately 40,000 m. (25 mi.).

Yet the percentage composition of a gas does not alone determine its molecular concentration. This is illustrated by the fact that a man breathing air suffers from oxygen lack at an altitude of 5,500 m. (18,000 ft.), and without an extra source of oxygen will die if he goes higher than about 7,500 m. (25,000 ft.). (*See* HYPOXIA.) The percentage of oxygen is still 20.95, but its molecular concentration is much lower than at sea level. This is because there is less atmosphere pressing down from above, hence the barometric pressure is less, and the molecules of oxygen and other gases are spread farther apart.

John Dalton (1766–1844) explained this behaviour of gases by an expression which now bears his name. According to Dalton's Law of Partial Pressures, in a mixture of gases each gas behaves as if it alone occupied the total volume of the gas mixture, and exerts a pressure, its partial pressure, independent of the other gases present. The sum of the partial pressures of the individual gases equals the total pressure of the gas mixture. At a given temperature, the partial pressure provides a measure of the molecular concentration of a gas. The partial pressure, P, of a gas, G, may be calculated by Dalton's Law as follows:

$$P_G = \frac{(\%\text{ concentration of G in dry gas})}{100} \text{ (total pressure of dry gases)}$$

If air at sea level were dried, then the partial pressures of its constituent gases would be:

$P_{O_2} = 20.95/100 \times 760 = 159.2$ mm. of mercury (Hg)
$P_{CO_2} = 0.03/100 \times 760 = 0.2$ mm. Hg
$P_{N_2} = 78.08/100 \times 760 = 593.4$ mm. Hg
P other gases $= 0.94/100 \times 760 = 7.2$ mm. Hg
Total of partial pressures = 760.0 mm. Hg = barometric pressure

However, air normally contains some water vapour, which exerts a partial pressure of its own. The air in all parts of the lungs is saturated with water vapour, the tension of which is related to the temperature, being equal to 47 mm. at 37° C (= 98.6° F, body temperature). This vapour tension must be subtracted from the barometric pressure in order to get the total pressure of the dry gases in the lung. One may then calculate the partial pressures of any dry gas, G, in the lung from Dalton's Law (percent concentration of each constituent gas being expressed always in terms of volumes of dry gas per 100 volumes of the dry gas mixture) as follows:

$$P_G = \frac{(\%\text{ concentration of G})}{100} \text{ (Bar. P. } -47)$$

The French physiologist Paul Bert pointed out in 1878 that it was the partial pressure and not the percent composition that determines the physiological effects of a gas. Dalton's Law, he indicated, explains why it is difficult to breathe at high altitudes. The barometric pressure falls, and with it the partial pressures of all the gases. Only that of oxygen affects respiration, the P_{CO_2} in atmospheric air being negligibly low and the nitrogen gas inert. At 5,500 m. (18,000 ft.) the P_{O_2} in moist air entering the lung has fallen to only 69 mm., which is not enough to oxygenate the blood adequately. Even breathing pure oxygen, the P_{O_2} has again fallen to 69 mm. at an altitude of 13,400 m. (44,000 ft.), which is close to the "ceiling" above which a man cannot go without a pressurized cabin or flying suit.

The data in the table illustrate what happens to atmospheric air as it is breathed into the lungs. In the moistened air of the trachea the P_{O_2} is (20.95/100) (760–47) = 150 mm. However, less than this tension of O_2 is available for diffusion into the blood because the incoming air is diluted by the CO_2 leaving the alveoli, while at the same time the O_2 diffuses out of the air, further reducing the O_2 tension. Thus, there is exchanged (in almost equal quantities) O_2 for CO_2, as the incoming gas moves on down into the depths of the lung, into the alveolar ducts, the atria which open into the alveoli, and finally the alveoli themselves. The air here is called alveolar gas and is defined as gas which, in contact with the respiratory epithelium, is essentially in equilibrium with the blood leaving the lung. That is, the P_{O_2} in the gas is almost the same as in the purified blood, and similarly for the P_{CO_2}.

Pressures of Gases in the Respiratory Tree and in the Tissues, expressed in mm. Hg.

Sample of gas	P_{O_2}	P_{CO_2}	P_{N_2}*	P_{H_2O}	Total P
Inspired	158	0.3	596	5.7	760
Tracheal	150	0.3	562.7	47	760
Expired	116	32	565	47	760
Alveolar	100	40	573	47	760
Arterial blood	95	40	573	47	755
Venous blood	40	46	573	47	706
Tissues	30	50	573	47	700

*Includes argon and the trace gases.
Modified from J. F. Fulton (ed.), *A Textbook of Physiology*, 17th ed., p. 827 (1955).

Thanks to the researches of Haldane, it is easy to sample alveolar gas in a normal person. The subject has only to breathe out forcefully through a long rubber tube, then the last portion of the gas exhaled is withdrawn and the percentage of carbon dioxide and oxygen present can be determined by analysis. From these data the corresponding partial pressures may be calculated by means of Dalton's Law.

As indicated in the table, the P_{O_2} of alveolar gas = 100 mm., P_{CO_2} = 40 mm. These values are remarkably constant at rest at sea level and deviate only slightly during exercise. This, as will be shown below, results from the fact that the respiratory centres in the brain seem to be set to a P_{CO_2} close to 40 mm.

Respiratory Dead Space and Alveolar Ventilation.—As indicated in the table, expired gas has a higher P_{O_2} and lower P_{CO_2} than alveolar gas, because it consists of alveolar gas mixed with atmospheric air from the respiratory dead space. This term refers to that inspired air which does not come in contact with the alveolar membranes but simply fills the air passages, including the nose, pharynx, trachea, bronchi, and bronchioles. At the beginning of expiration this atmospheric air is simply breathed out again, having taken no part in respiratory exchange. The dead space can be measured anatomically in a cadaver by filling the air passages with water, which presumably goes down to but does not enter the alveoli. The volume of the water is measured and equals, on the average, 150 ml. In living subjects, the anatomical dead space may be determined by measuring the volume of gas exhaled before the tension of carbon dioxide rises sharply. Indicating the boundary between dead space and alveolar gas, this rise is detected by a rapid-acting gas analyzer which operates on the physical principle that carbon dioxide absorbs infrared light.

The physiological dead space is more closely related to the efficiency of ventilation because it includes not only the gas in the anatomical dead space but also that ventilating alveoli with relatively poor or no blood flow. It may be calculated from the partial pressure of carbon dioxide, as determined by chemical analysis in (1) arterial blood, (2) expired gas, and (3) inspired gas (P_{CO_2} is essentially zero when breathing air), and from the tidal volume (V_T), using the following equation introduced by the Danish physiologist Christian Bohr:

$$V_D = \frac{V_T\ (P_{CO_2}, \text{ arterial blood} - P_{CO_2}, \text{ expired gas})}{(P_{CO_2}, \text{ arterial blood} - P_{CO_2}, \text{ inspired gas})}$$

For example, P_{CO_2} in arterial blood was 40 mm., in expired gas 28, and in inspired gas 0, and tidal volume was 600 ml. Then:

$$V_D = \frac{600\ (40 - 28)}{(40 - 0)} = 180 \text{ ml.} = \text{the physiological dead space}$$

The volume of gas effectively ventilating the alveoli with each breath is equal to the difference between the tidal volume and the physiological dead space, and when multiplied by the number of breaths per minute (f) gives the alveolar ventilation, $\dot{V}_A$, expressed in litres per minute. Or, in arithmetic form, $\dot{V}_A = (V_T - V_D)\,f$. It is $\dot{V}_A$, rather than the total volume of gas exhaled per minute ($\dot{V}_E$), that determines how well the air in the lungs is being renewed. With rapid, shallow breathing, $\dot{V}_E$ must be larger in order to provide a given alveolar ventilation than with slow, deep breathing. This point is illustrated if we resort to a *reductio ad absurdum*, decreasing the tidal volume to that of the dead space. Then $(V_T - V_D) = 0$, and regardless of how rapid the breathing is, alveolar ventilation is zero. Of course this situation is not compatible with life; no oxygen could reach the lung or carbon dioxide

leave until the tidal volume was again increased. In the rapid, shallow panting of dogs, V_T is only slightly greater than V_D, the panting serving to move large volumes of air over the tongue to facilitate cooling by evaporation, without V_A being increased to the point where the lungs are overventilated and the blood carbon dioxide tension lowered below normal.

CARRIAGE OF OXYGEN AND CARBON DIOXIDE BY THE BLOOD

An average man at rest uses 250 ml. (more than $\frac{1}{2}$ pt.) of pure oxygen per minute and gets rid of almost as much carbon dioxide, the chief by-product of the combustion of foodstuffs. These two gases are transported in the blood largely because of the activity of hemoglobin (symbol Hb) one of the most remarkable chemical substances produced during the course of evolution. Located inside the red blood cells, hemoglobin combines reversibly with oxygen as indicated by the reaction: $Hb + O_2 \rightleftarrows HbO_2$. Over 96% of the oxygen is carried in this form, the rest being dissolved in the blood.

A much smaller fraction (about 25%) of the carbon dioxide produced is carried in direct combination, as so-called carbamino hemoglobin; most of the CO_2 is transported as the result of a series of chemical reactions dependent on the special properties of hemoglobin.

Oxygen Dissociation Curve.—As the arterial blood passes through the tissues, each 100 ml. gives up about 5 ml. of O_2; as it does so the P_{O_2} falls from 100 mm. to near 40, that of venous blood. This unloading of large quantities of oxygen as a result of a relatively small fall in P_{O_2} is one of the unique properties of hemoglobin. Without it, the oxygen could theoretically be carried in dissolved form, much as carbon dioxide is dissolved in soda water. But only 0.2 ml. of O_2 would be given up under conditions comparable with those outlined above, and 25 times more blood would have to be pumped through the body, requiring an impossibly large circulatory system.

The quantity of oxygen combining with hemoglobin at various tensions of O_2 is given by an oxygen dissociation curve (fig. 5). Each point on the curve is obtained by exposing a sample of blood to a gas containing oxygen in a glass vessel. The vessel is rotated at body temperature long enough to equalize the oxygen tensions in blood and gas. The volume of oxygen in the blood sample and the P_{O_2} of the gas are then determined by chemical analysis. For example, the hemoglobin in 100 ml. of blood was found to hold 14.8 ml. O_2 at a P_{O_2} of 40 mm. Another portion of the same blood was exposed to a gas with a P_{O_2} high enough (150 mm.) to oxygenate essentially all of the hemoglobin. The latter sample held 20 ml. O_2 per 100 ml. The oxygen saturation of the first sample was therefore 74% (14.8/20 × 100). Thus, 74% of the hemoglobin molecules were combined with oxygen, the remaining 26% being reduced; *i.e.*, without oxygen. (The term oxygen saturation refers only to the oxygen combined with hemoglobin and not to dissolved oxygen.)

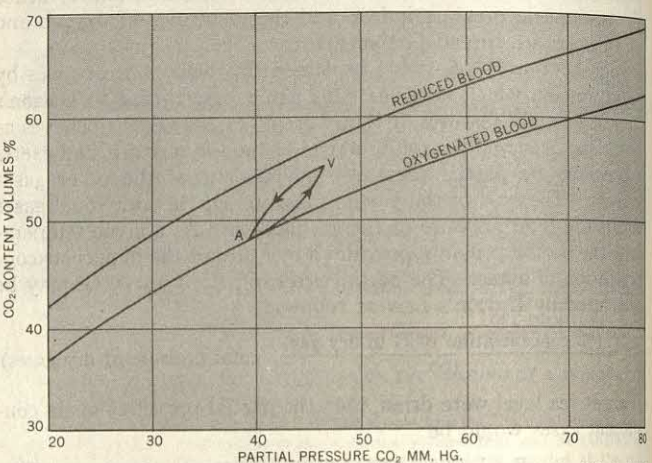
FIG. 5.—OXYGEN DISSOCIATION CURVES FOR WHOLE BLOOD

Increase in P_{CO_2} shifts curve to right, an illustration of the Bohr effect. Loop labeled A (arterial) and V (venous) shows approximate actual curve followed in the body

Because of the unique properties of hemoglobin, the carriage of oxygen is related to that of carbon dioxide and vice versa. Each process helps the other. This is illustrated by the fact that the position of the oxygen dissociation curve is shifted to the right by an increase in the tension of carbon dioxide (fig. 5). That is, adding CO_2 to the blood tends to drive oxygen out. This is known as the Bohr effect. It helps to deliver oxygen to the tissues. For a given fall in P_{O_2} more O_2 is released than if a dissociation curve at constant P_{CO_2} were followed. Conversely, as CO_2 is given off in the lungs, the uptake of O_2 is facilitated.

CO_2 Dissociation Curve and Carriage of CO_2.—There is a converse of the Bohr effect: adding oxygen to blood drives carbon dioxide out. This, known as the Haldane effect, may be demonstrated by means of carbon dioxide dissociation curves, determined first for oxygenated and then for reduced blood. It will be noted (fig. 6) that the latter holds considerably more CO_2 at a given P_{CO_2} than the former. Carriage of carbon dioxide is facilitated by the Haldane effect in much the same manner as the carriage of oxygen is facilitated by the Bohr effect. As the arterial blood gives up part of its oxygen to the tissues it is able to take up more carbon dioxide for a given increase in P_{CO_2} than if it remained fully oxygenated. This is shown in fig. 6 by the loop labeled "A" (arterial) "V" (venous), which describes the pathway followed by the blood as it goes from artery to vein.



FROM J. P. PETERS AND D. D. VAN SLYKE, "QUANTITATIVE CLINICAL CHEMISTRY," VOL. I, WILLIAMS & WILKINS CO., BALTIMORE, 1931

FIG. 6.—CARBON DIOXIDE DISSOCIATION CURVES FOR REDUCED AND OXYGENATED BLOOD

Though the CO_2 dissociation curve makes it possible to predict the volume of CO_2 contained in blood at a given P_{CO_2}, it does not describe how carbon dioxide is carried in the blood. Actually it is carried in several ways, as follows:

1. About 10% is carried in dissolved form (as carbon dioxide is in soda water).

2. About 25% is in direct combination with hemoglobin as carbamino hemoglobin.

3. About 10% is carried as carbonic acid (H_2CO_3). This splits into hydrogen ions (H^+) and bicarbonate ions (HCO_3^-). The latter, nontoxic ions, are carried inside the red blood cell and in the plasma (the clear portion of the blood). Hydrogen ions, however, which in their active state would cause damage to tissue cells, are buffered; *i.e.*, the ions are "soaked up" by the blood proteins including hemoglobin. A buffer solution (*see* HYDROGEN IONS: *Buffer Action*) resists change in acidity by combining with added hydrogen ions and essentially inactivating them. Because not all of the added acid can be removed from the solution, the acidity does rise slightly, but only a fraction of what it would were the buffer not present.

4. The remaining 55% or so of the carbon dioxide is also carried as carbonic acid, except that the hydrogen ions are buffered in a special way by the hemoglobin as the latter gives up its oxygen. This process is related to the Haldane effect, and depends on the fact that when hemoglobin gives up its oxygen it becomes less acid, and can therefore take up most of the hydrogen ions produced in the tissues without any change in acidity at all. This is known as the isohydric exchange.

Were carbon dioxide carried entirely in solution, no hemoglobin being present, the hydrogen ions produced from carbon dioxide would make the venous blood 800 times more acid than the arterial, the pH (hydrogen ion concentration, a measure of acidity) changing from 7.4 to 4.5. In actual fact the pH falls only 0.05 units, thanks to the two buffering mechanisms described.

The series of chemical reactions involved in the transport of

oxygen and carbon dioxide by the blood is shown in fig. 7. Because of the participation of chloride ions in this process, it is often referred to as the chloride shift.

The sequence of events is as follows: In the tissues, foodstuffs such as carbohydrates are oxidized, the by-products of this energy-producing reaction being carbon dioxide and water. The carbon dioxide produced immediately dissolves in the water of the blood, and 10% of it will be carried in that form to the lungs. Now, dissolved carbon dioxide reacts with water to form carbonic acid: $CO_2 + H_2O \rightleftarrows H_2CO_3$. This hydration of carbon dioxide takes place very slowly in water or in plasma. For this reason most of the carbon dioxide, in the form of molecular carbon dioxide, diffuses through the plasma and into the red blood cells. In the latter there is a high concentration of the enzyme carbonic anhydrase, which catalyzes (*i.e.*, speeds up) the hydration of carbon dioxide to carbonic acid inside the red cells. The carbonic acid ionizes slightly; that is, it splits into positively and negatively charged particles as follows: $H_2CO_3 \rightleftarrows H^+ + HCO_3^-$. The hydrogen ions are immediately taken up by the hemoglobin by the buffering mechanisms described.

A portion of the dissolved carbon dioxide combines directly with hemoglobin to form carbamino hemoglobin. In the process, a hydrogen ion must be buffered by the hemoglobin.

More and more bicarbonate ions accumulate inside the red blood cell and are carried to the lung. A somewhat greater portion is carried as bicarbonate in the plasma, having diffused out of the red cell as a result of increasing concentration.

The plasma now contains excessive negative charges in the form of bicarbonate ions. Unless there is an equal number of positive and negative charges in any solution, enormous electrostatic forces will be built up. Compensation for such inequality always occurs. In this case a number of negatively charged chloride ions, equal

FIG. 7.—SEQUENCE OF CHEMICAL EVENTS BY WHICH CO_2 IS CARRIED BY THE BLOOD FROM TISSUES TO LUNGS. THE REVERSE PROCESSES OCCUR IN THE LUNGS AS THE BLOOD GIVES OFF CO_2 AND TAKES UP O_2

to that of the bicarbonate ions entering the plasma, are drawn by electrostatic forces into the red blood cell.

These events take place in the blood passing through the tissues. The reverse processes occur in the lungs as the blood gives off carbon dioxide and takes up oxygen.

RESPIRATORY CENTRES AND NERVOUS ORIGIN OF RESPIRATION

Since the early part of the 19th century it has been known that a small region in the medulla oblongata (the basal part of the brain) is essential to breathing and hence to life. Occupying in a man a volume no larger than that of a good-sized grape, the respiratory centres consist of motor nerve cells imbedded in a crisscrossing matrix of nerve fibres. This reticular formation, as it is called, serves to coordinate the activity of the widely spaced respiratory muscles.

Three basic experimental approaches have been used in order to analyze in anesthetized animals the respiratory function of various parts of the medulla oblongata and also of the region forward of it called the pons. These are: (1) effects of removal or localized destruction of discrete areas; (2) effects of stimulation by electric shocks or injected chemical solutions; and (3) recording of action potentials, the tiny electrical impulses set up by all active nerve cells. In spite of extensive studies, in the mid-1960s it still was not entirely clear (*a*) how the impulses from the respiratory neurons originate, or (*b*) why these bursts of impulses are rhythmically interrupted every few seconds at a rate corresponding to that of breathing.

With regard to (*a*) it is not surprising that reflex activity has been considered. When, for example, a person steps on a nail, nerve impulses ascend to the spinal cord and stimulate motor nerve cells there so that the foot is reflexly (*i.e.*, automatically) withdrawn. As early as 1832 the English physiologist Marshall Hall stated that the medullary respiratory centres were not spontaneously active but were merely stimulated reflexly by various sensory nerves. As evidence, he cited the familiar observations that dashing cold water in the face, bathing in the cold sea, or pinching certain nerves during an experiment on an animal all cause "an act of inspiration to be excited."

The modification of respiration by these strong stimuli is far different from the regular breathing of rest or sleep, which originates in complex nerve networks in the medulla and adjacent pons. Yet controversy still exists as to whether this rhythm persists after all incoming impulses have been cut off from the brain above, from structures sensitive to the chemical composition of the blood, and from the spinal cord below.

There is undisputed evidence that mammalian cardiac muscle cells, in particular those located in the cardiac "pacemaker," became spontaneously depolarized, thus generating, without the need for nervous activity, the periodic beat of the heart. Nerve cells in regions such as the cerebral cortex presumably can be stimulated by fluctuating potentials produced by firing of neighbouring neurons. R. Gesell suggested that truly spontaneous activity of respiratory neurons might exist, as the result of a steady current flowing in the external medium from the base of the axon (the nerve fibre) back to the cell body in sufficient strength to depolarize and thus stimulate the nerve cell respectively. (*See* also NERVE CONDUCTION.)

Such a mechanism has not yet been demonstrated experimentally. Even if it had been, the steady firing of respiratory motor neurons needs to be modulated so that expiration follows inspiration in a regular sequence in order to produce rhythmic respiration. Two divergent theories have been proposed and extensively evaluated. The first assumes that the medullary respiratory centres are not by themselves inherently rhythmic, but produce only a steady stream of impulses. These are said to be periodically inhibited or turned off by influences outside the medulla, much as in a steam engine the flow of steam to the moving piston is turned on and off by the valve. According to the second theory the neurons of the respiratory centres have the inherent capacity to fire in regularly repeated bursts, apart from outside influences. Such a process resembles the ticking of a watch, with the balance wheel, driven by the escapement, turning to and fro at its own natural rhythm by a "pacemaker" action.

Evidence for the first theory goes back to 1868, when the Viennese physiologists Ewald Hering and Josef Breuer discovered that inflation of the lungs with a bellows caused inspiratory activity to be inhibited, the resulting apnea, or lack of breathing, lasting for a considerable period. They found that this effect was abolished when the tenth cranial nerves (the vagi) were cut. It has since been shown that receptors in the lung are stimulated by inflation, sending impulses up the vagi which cause the inhibition. The Hering-Breuer reflexes could, as their discoverers pointed out, permit a tonic (steady) inspiratory drive to be converted into a rhythmic process. Supporting evidence was obtained in 1887 by M. Marckwald, who discovered that, if the pons is transected in its midregion, breathing remains normal as long as the vagi are intact. If they are then cut, the experimental animal takes a deep breath and holds it until he dies. But if the brain stem is initially severed higher up, leaving the entire pons intact, the animal continues to breathe even after the vagi are cut, though more slowly and deeply than before. Thus, Marckwald had ob-

tained evidence for a second inhibitory mechanism, in addition to the vagal one, located in the rostral (forward) part of the pons. Though either mechanism could convert the tonic inspiratory drive into a rhythmic process, it was the vagal one that was considered to be involved in normal breathing.

Much evidence in support of this periodic inhibition theory has subsequently been gathered. T. Lumsden in 1923 located and named: (1) the pneumotaxic centre, located in the rostral pons, responsible for inhibiting the steady activity of (2) the apneustic centre, in the caudal (rearward) pons, responsible for sustained inspiration, which Lumsden called apneusis.

As a result of a comprehensive series of studies on the medullary-pontine respiratory complex, R. F. Pitts in the 1930s and '40s located by electrical stimulation a centre responsible for inspiratory activity in the reticular formation of the medulla, and a separate expiratory centre situated close to it. He obtained evidence that the inspiratory centre was dominant to the expiratory centre, the two being interconnected by nerve fibres so that stimulation of one caused inhibition of the other, an example of reciprocal innervation as in the spinal cord.

Confirming the existence of apneusis after midpontine section and vagotomy, Pitts like Marckwald concluded that the medullary respiratory centres were not inherently rhythmic, sustained activity of the inspiratory centre being converted to periodic breathing by the vagal stretch reflexes from the lungs and, following vagotomy, by the pneumotaxic centre. This concept of the genesis of rhythmic respiration became widely accepted during the next ten years, tending almost entirely to replace the "pacemaker" theory. In the late 1940s and early '50s, however, H. E. Hoff and C. G. Breckenridge produced evidence in favour of the latter theory. They pointed out, as had some of their predecessors, that apneusis was neither permanent nor total after midpontine section and vagotomy. Superimposed on the deep, prolonged inspirations were small, rhythmic respiratory movements capable of keeping the experimental animal alive for an hour or more. More important, when they sectioned the brain stem below the pons in order to isolate the medulla, rhythmic respiration, sometimes normal though often gasping in character, appeared. S. C. Wang concluded, in agreement with Hoff and Breckenridge, that inherent medullary rhythmicity has a role in originating the normal respiratory rhythm. However, this may be profoundly modified by the apneustic centre, located in the pons, which tends to produce sustained inspiratory activity, and by the inhibitory action of vagal afferents and of the pneumotaxic centre, in the nerve cells of which Wang recorded, by means of microelectrodes, bursts of action potentials correlated with various phases of respiration.

G. C. Salmoiraghi and B. D. Burns failed to observe such activity in the pneumotaxic centre and therefore tended to minimize its importance in the genesis of the respiratory rhythm. They and Wang agree that motor nerve cells discharging during inspiration are closely mingled with cells discharging during expiration—both groups, inspiratory and expiratory, being linked together by nerve fibres so that activity in one cell spreads rapidly to others of the same group. It is also clear, as stated previously by Pitts, that activity of the inspiratory cells tends to decrease or inhibit the activity of the expiratory cells, and vice versa—an example of reciprocal innervation (*see* SPINAL CORD: *Physiology*).

Salmoiraghi and Burns found that the firing of medullary respiratory motor neurons decreased to only 10% of normal when cuts were made through the brain stem in order to eliminate all afferent impulses. They concluded that activity of the respiratory centres depends on excitation from nonrespiratory sources and also from neural structures sensitive to chemical stimuli such as CO_2 in the blood. Afferent impulses initiate firing in an inspiratory neuron and the activity spreads, causing inspiration to occur and at the same time inhibiting the activity of expiratory motor neurons. The inspiratory activity dies out, and the expiratory cells take over. The system swings one way or the other, like a metronome or a "flip flop" electronic multivibrator circuit. If respiratory movements are made to stop by excessive anesthesia or by lowering blood CO_2 concentration, either inspiratory cells or expiratory cells are found to be discharging continuously; the cells

FIG. 8.—SCHEMATIC REPRESENTATION OF THE MEDULLARY-PONTINE RESPIRATORY CENTRES INVOLVED IN RHYTHMIC BREATHING

Arrows show direction of nerve impulses involved in the periodic inhibition theory for the origin of rhythmic breathing

of both groups are never silent. Much research involving electrical stimulation, recording of action potentials and steady potentials, localized destruction, and correlated histological examination is necessary before a clear understanding of rhythmic breathing can be obtained.

Fig. 8 summarizes the localization of function of the medullary-pontine respiratory centres as outlined above.

REGULATION OF PULMONARY VENTILATION

Chemical Control of Breathing.—The respiratory system provides the body with oxygen and eliminates carbon dioxide. It is also one of the chief mechanisms maintaining a relatively constant internal environment, a condition essential to the survival of complex organisms, as stated by the French physiologist Claude Bernard (1813–1878). Thus, it counteracts the threat of low oxygen or high carbon dioxide in the environment, and minimizes excess acidity or alkalinity of the blood caused by metabolic disorders. It performs these tasks by constantly regulating the volume of air breathed, called the pulmonary ventilation, which is the product of the rate and depth of respiration.

This process is called the chemical control of breathing because it is carried out by specialized nerve cells, sensitive to the chemical composition of the blood, which vary the activity of the medullary respiratory centres. These cells are called chemoreceptors, or sometimes chemostats, because they stabilize the internal chemical environment much as a thermostat maintains a constant temperature in a room.

Though a man will die if he is deprived of oxygen for only a few minutes, his pulmonary ventilation is normally regulated by the tension of carbon dioxide in the blood rather than by that of oxygen. These facts were first discovered by Haldane and J. G. Priestley in 1905. Having developed a method for obtaining alveolar gas (which has essentially the same P_{CO_2} and P_{O_2} as arterial blood), they proceeded to analyze hundreds of samples obtained from normal subjects at various altitudes relative to sea level, and consequently at varying barometric pressures, even including that in a compressed air chamber used to treat certain respiratory disorders. In the laboratory at Oxford, at a barometric pressure (P_B) of 755 mm., the alveolar P_{CO_2} was 42.1 mm. It remained within 1.4 mm. of that figure on a mountain 1,360 m. (4,400 ft.) high ($P_B = 646$), at the bottom of a mine ($P_B = 832$), and in the compressed air chamber ($P_B = 1{,}260$). Yet the corresponding alveolar oxygen tensions varied widely, being 99 in the laboratory and 79, 115, and 203 mm., respectively, at the other locations. These simple data, from what has come to be known as a classic

experiment in respiratory physiology, indicate that the pulmonary ventilation is normally regulated by the P_{CO_2} and not by the P_{O_2}.

Confirmatory evidence was obtained by adding small quantities of carbon dioxide to the inspired air. With 3% CO_2, the alveolar ventilation was doubled, the alveolar P_{CO_2} rising only 1.5 mm., indicating the extreme sensitivity of the respiratory centres to increases in P_{CO_2}. The increase in ventilation occurring when carbon dioxide is inhaled is compensatory, tending to minimize a rise in alveolar P_{CO_2}.

Haldane then reasoned that if a small rise in alveolar P_{CO_2} would double the ventilation, a corresponding fall might be expected to cause breathing to cease. This was investigated by having subjects hyperventilate (*i.e.*, breathe deeply and rapidly), thereby reducing the alveolar P_{CO_2} from the normal value of 40, down to 15 or even 10 mm. Apnea (absence of breathing) invariably ensued, its duration, often of several minutes, being related to the degree of lowering of the P_{CO_2}. That it was due to this factor was shown by keeping the P_{CO_2} essentially normal by having the hyperventilating subject breathe air containing 5% carbon dioxide, following which no apnea occurred. Nor did it occur on quietly breathing pure oxygen, thus eliminating increased P_{O_2} as a cause of posthyperventilation apnea as had been suggested by a previous investigator, who had believed that respiration was normally regulated by the oxygen tension of the blood.

That oxygen lack is at best a poor stimulus to respiration, by no means as effective as a rise in carbon dioxide, was emphasized by Haldane. Little increase in ventilation occurs until the alveolar P_{O_2} falls from its normal value of 100 mm. down to about 70 mm., equivalent to an altitude of between 1,800 and 2,100 m. (6,000–7,000 ft.). Yet the hyperpnea cannot be accounted for in terms of CO_2, since the tension of the latter falls, by 10 mm. or more, during hypoxia. It was proposed, but never proved, that lactic acid might be the stimulus, the lack of oxygen causing its production inside the medullary respiratory centres. These centres were long known to be the site where carbon dioxide exerted its chief influence on respiration, and it was natural to expect hypoxia to act there too.

The explanation was not forthcoming until the early 1930s, when Corneille Heymans and his associates demonstrated the existence of respiratory reflexes originating from the carotid arteries in the neck. Close to where the latter branch into the internal and external carotid arteries lie, first, a set of pressoreceptors important in the regulation of blood pressure and also influencing respiration; and, second, a set of chemoreceptors sensitive to decreases in the oxygen tension of arterial blood and to a lesser extent to rises in P_{CO_2} and acidity. Similar sets of presso- and chemoreceptors are located at the arch of the aorta. The carotid and aortic bodies or glomera, as these chemoreceptors are called, consist of rounded epithelioid receptor cells, richly innervated and provided with a profuse supply of arterial blood. Impulses are generated in the receptor cells when the P_{O_2} falls sufficiently. Carried by nerves to the medullary respiratory centres, these impulses increase the activity of the centres and thus increase pulmonary ventilation.

That oxygen lack stimulates respiration almost entirely by way of the peripheral chemoreceptors has been shown by the fact that after their nerves are cut the inhalation of nitrogen almost always decreases respiration, due to depression of the medullary respiratory centres, whereas normally ventilation is more than doubled.

Though these chemoreceptors serve chiefly an emergency function, normal respiration being controlled mainly by the action of CO_2 or acid (*see* below) on the medullary respiratory centres, evidence for a significant degree of ventilatory drive due to O_2 even at sea level has been obtained by P. Dejours.

It is of some interest to speculate what would happen were respiration in man controlled not largely by P_{CO_2} but by P_{O_2}, as it appears to be in lizards, snakes, and fishes. Assuming the alveolar P_{O_2} to be held at 100 mm., the normal value at sea level, the pulmonary ventilation would be approximately doubled on the 1,360-m. mountain referred to by Haldane, and would be reduced to less than one third in the pressure chamber. Values for alveolar P_{CO_2} would be approximately 20 and 140 mm., respectively. Corresponding acidity of arterial blood, expressed in terms of pH, would be 7.6 (alkaline) and slightly below 7 (markedly acid). Such marked deviations from the normal P_{CO_2} of 40 and pH of 7.4 would probably lead to muscular spasms, known as tetany, in the first instance and to CO_2 narcosis and anesthesia in the second.

Nature of the Chemical Stimulus to the Respiratory Centres.—After Haldane's discovery of the importance of carbon dioxide in the control of respiration, physiologists sought to find its mode of action. When, as the result of new measuring techniques, data relating rise in arterial acidity to rise in P_{CO_2} became available, H. Winterstein, and Haldane himself, came to believe that the pulmonary ventilation was regulated by the arterial hydrogen ion concentration rather than by the P_{CO_2}. This reaction theory, as it came to be called, gained further support from the fact that in metabolic acidosis, as in diabetes, respiration is increased even though the P_{CO_2} is below its normal value of 40 mm.

There were, however, experiments of a quantitative nature which cast doubt on the reaction theory. Marius Nielsen found that for a given increase in acidity produced by the acid-producing salt ammonium chloride, the hyperpnea was trifling compared to that accompanying inhalation of CO_2. Similarly, D. R. Hooker perfused the medulla of an anesthetized animal with blood kept at constant acidity, first by adding hydrochloric acid and second by adding carbon dioxide, the increases in pulmonary ventilation being 128% and 3,069%, respectively. The inference to be drawn from these and similar experiments is that carbon dioxide has a marked stimulating effect on respiration in addition to its property of increasing the acidity of the blood.

That a special property of molecular carbon dioxide did not need to be postulated was illustrated by the experiments of M. H. Jacobs in the early 1920s. The flowers of certain carnations were known to be blue in alkaline media and red in acid. Blue flowers immersed in acid solutions remained blue for long periods, but in solutions saturated with carbon dioxide and buffered to the alkaline side with sodium bicarbonate, the flowers turned red immediately. The explanation was that dissolved carbon dioxide was able to diffuse freely into the interior of the cell, rendering it acid. With the flowers in acid solution, however, the acid went in very slowly, because the cell membrane was relatively impermeable to the positively charged hydrogen ions. The same effect was observed in living sea urchin eggs. Jacobs' investigations made it clear that the acidity inside the cells of the respiratory centres might differ widely from that of the arterial blood.

On the basis of these findings, Winterstein modified his original reaction theory in order to identify the acidity inside the cells of the respiratory centres, rather than that in the blood, as the unique stimulus to respiration. Gesell pursued this idea and found evidence for disparities between the acidity of the blood and that of the cerebrospinal fluid which surrounds the central nervous system, including the medullary respiratory centres. These differences are known to be due to the blood-brain barrier, composed of the meninges covering the brain, which prevent free passage of many substances, including hydrogen ions.

In spite of numerous investigations, there remained two schools of thought regarding the "unique" chemical stimulus to the respiratory centres, if indeed there is one. The Scandinavian group, led originally by A. Krogh and later by Nielsen, advocated P_{CO_2} as the stimulus, the hyperpnea of metabolic acidosis being explained on the basis of increased sensitivity of the respiratory centres to P_{CO_2} as a result of the acidosis. On the other hand, Winterstein, Gesell, and others advocated intracellular pH.

An ingenious attempt to resolve the dilemma is provided by the multiple factor theory of J. S. Gray, according to which each chemical stimulus to respiration acts in its own right, the existing level of ventilation being the resultant of the additive effects of the known stimuli, namely P_{CO_2}, hydrogen ions (acidity) and, during hypoxia, P_{O_2}. For example, the marked response to breathing CO_2 could be due to the effect of increased P_{CO_2} plus that of the increased acidity produced by adding CO_2 to the blood. On the other hand, the much smaller response that accompanies an equal degree of acidity produced by metabolic acidosis could be due to the difference between a stimulus, increased acidity, and an

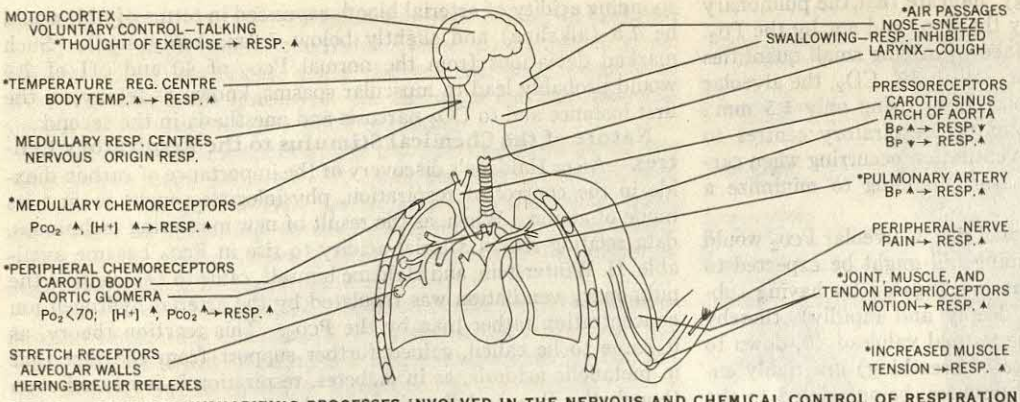

FIG. 9.—DIAGRAM SUMMARIZING PROCESSES INVOLVED IN THE NERVOUS AND CHEMICAL CONTROL OF RESPIRATION

Asterisks indicate factors probably contributing to the increased breathing of exercise. Horizontal arrows (→) denote "leads to"; vertical arrows indicate increase (↑) or decrease (↓) in the factor referred to. BP is the symbol for blood pressure

antagonist, decreased P_{CO_2} (below normal in this condition). In other words, the addition is algebraic in this instance.

The concept of an antagonist—*i.e.*, a less than normal contribution of a respiratory stimulus—though implicit in the finding by Haldane of apnea following hyperventilation when the P_{CO_2} was only slightly reduced, is one of the keystones of Gray's theory. According to him, there is no unique stimulus, all three combining their effects.

I. R. Leusen showed (1954) that perfusion of the cerebral ventricles (cavities within the brain, filled with cerebrospinal fluid) with solutions possessing increased P_{CO_2} or acidity increased pulmonary ventilation. H. H. Loeschcke later emphasized the importance of acidity rather than P_{CO_2} in mediating the response, and R. A. Mitchell found that the acid-sensitive regions were located bilaterally on the ventrolateral surfaces of the medulla oblongata. It seems clear that these chemosensitive areas play a major role in mediating the normal respiratory response to CO_2 and possibly to "fixed" acid, *e.g.*, lactic acid, in the blood.

Regulation of Ventilation During Physical Exercise.—Haldane proposed that carbon dioxide was responsible for the increase in breathing that accompanies exercise. The experimental data, however, have not supported him. The highest ventilation produced by increasing the P_{CO_2} is about 70 l. per minute during breathing of 7.5% CO_2, the alveolar P_{CO_2} then being 60 mm., which is 20 mm. above normal. In severe exercise, not only is the ventilation considerably higher, 100 to 120 l. per minute, but, what is more striking, the P_{CO_2} is actually below its normal value of 40 mm. Hence an elevated P_{CO_2} cannot possibly explain the great increases in ventilation observed during severe exercise, and can account only partially for the hyperpnea of moderate exercise, when the P_{CO_2} is only slightly (2 to 4 mm.) above normal. Nor does the P_{O_2} fall markedly during exercise at sea level.

No known simple factor can explain the increase in ventilation occurring during exercise. Several stimuli appear to combine their effects and in such a way that the volume of air breathed increases in direct proportion to the increase in work done and the oxygen used. It is difficult to conceive of so precise a regulation without the intervention of a chemical factor which, produced as a result of the exercise, acts so as to increase the ventilation. Yet no such agent has been found. It is true that an increase in blood acidity occurs during severe exercise and could be a factor in that condition alone. An increase in sensitivity of the respiratory centres to P_{CO_2} has also been postulated. A rise in body temperature can produce such an increase, and the body temperature does rise 1° or 2° C (about 2° to 3½° F) or more during severe exercise. One investigator found an 11-l. increase in ventilation per 1° C rise in body temperature, due apparently to increase in sensitivity of the medullary respiratory centres to CO_2.

Nervous reflexes also contribute their share. Passive motion of the limbs in man or animals produces an increase in ventilation. The effect is abolished when the sciatic nerve to the leg is anesthetized by injection of procaine. The impulses responsible are known to arise in the special "position-sense" nerve endings (proprioceptors) located in joints and muscles, which permit an individual to tell whether a joint is extended or flexed and how much. F. F. Kao has stressed the importance of these afferent nervous impulses in the hyperpnea of exercise, induced in the lower extremities of anesthetized animals by electrical stimulation of the muscles. Breathing was not markedly reduced when the blood supply to the exercising muscles was provided entirely from another animal, but when the nerves from the limbs were cut, the hyperpnea was largely eliminated. P. Dejours has emphasized fast and slow components in the hyperpnea of exercise. Thus, immediately after the onset of muscular work, pulmonary ventilation increases abruptly, presumably as the result of the afferent nervous impulses referred to. There is then a delayed increase in breathing, possibly from chemical substances produced by the muscles. Similarly, after cessation of exercise there is a sudden, and then a gradual, decrease in ventilation.

Other nervous and chemical factors have been proposed to help account for the hyperpnea of exercise. These include afferent impulses initiated by movement of air through the smaller air passages, nerve impulses originating as the result of a rise in the blood pressure in the pulmonary artery, impulses produced by nerves sensitive to accumulation of metabolites such as lactic acid in exercising muscles, and rises in temperature of these muscles. Yet the experimental evidence for these other nervous and chemical reflexes is dubious at best. It is entirely possible that physiologists, in attempting to explain the hyperpnea of exercise, are at a stage similar to that existing before the discovery of the peripheral chemoreceptors, when many theories were proposed to account for the stimulation of ventilation by hypoxia, though none proved adequate.

Those reflexes that may contribute to the hyperpnea of exercise are marked by an asterisk in fig. 9. This diagram also gives some idea of the many other factors that influence breathing.

RESPIRATORY SYSTEM, ANATOMY OF. The respiratory tract, including all the organs concerned in the act of breathing, consists of the nasal cavities, pharynx (throat), larynx, trachea, bronchi and lungs (*see* fig. 1). In ordinary breathing the nasal cavities warm, moisten and filter the inspired air (*see* OLFACTORY SYSTEM). The pharynx, which lies between the nasal cavities and mouth, above, and the larynx and esophagus, below, is a transitional zone in which the pathways of swallowing and breathing cross each other (*see* THROAT). In certain mammals in which the sense of smell is all-important, breathing through the nose is made obligatory by an interlocking of the epiglottis and the uvula of the soft palate. In man there is a gap between the two; consequently food is sometimes misdirected into the larynx and windpipe.

Larynx.—When the physician looks into the throat with a laryngoscope, he is examining the mucous surfaces of the interior of the voice box. Reflected in his mirror are the structures shown in fig. 2: a lid-shaped epiglottis that can be folded backward over the larynx; the aryepiglottic folds, backward extensions of the epiglottis that help prevent spilling of food into the larynx; the pear-shaped piriform recess, through which food is guided into

the esophagus; the vallecula ("little valley"), which separates the epiglottis from the tongue; the ventricular folds or false vocal cords; and beneath them the glottis ("mouthpiece of a flute"). The latter consists of the vocal folds (or cords) and the slit between them, the rima glottidis.

The ventricular folds point downward and, when closed by action of sphincter muscles, form an exit valve that permits the

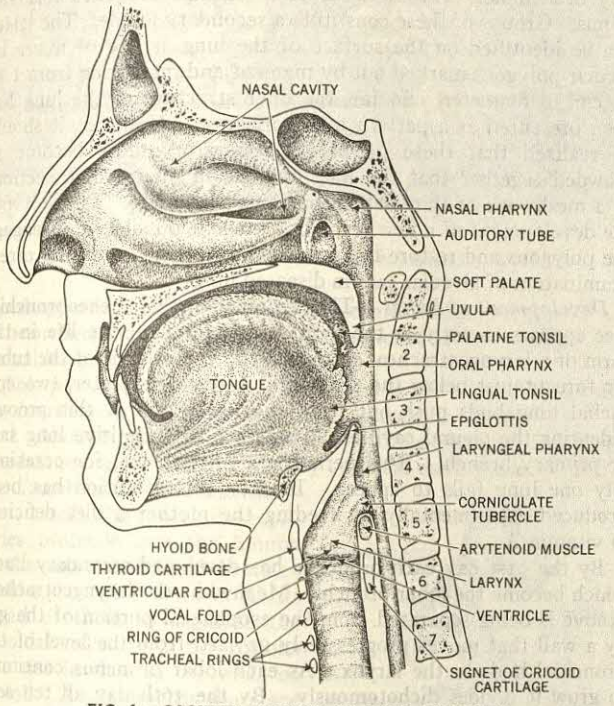

FIG. 1.—SAGITTAL SECTION OF HEAD AND NECK
Numbers indicate the cervical vertebrae

building up of abdominal pressure, as in straining at stool or in expulsion of the fetus. Coughing is produced by releasing the air explosively. Between the ventricular and vocal folds of each side is a pitlike cavity, the ventricle, which is prolonged into an appendix or saccule. In the great apes these saccules become enormous accessory organs of respiration.

The vocal folds are whiter than the ventricular folds because their areas of contact with each other are covered by stratified scalelike epithelium. These are the hard membranes that vibrate to produce sound. In breathing, they approach each other rhythmically. When closed by the surrounding muscles they form an inlet valve that prevents the entrance of air during fixation of the ribs for movements of the arms.

The physician examines the cords for evidence of inflammation, for the presence of tumours and for paralysis of muscles that regulate their action. They stretch across the interior of the voice box from the shieldlike thyroid cartilage, in front, to the vocal process of the pitcher-shaped arytenoid cartilage, behind (*see* fig. 1–3). The arytenoids are the key to the understanding of the movements of the cords. These cartilages slide and rotate upon the signet portion of the ringlike cricoid cartilage (*see* fulcrum, fig. 3), abducting or adducting the cords in response to muscles that insert upon the muscular process of each arytenoid. Tensing and loosening of the cords are produced, respectively, by the crico-thyroid muscles, which tilt the thyroid cartilage forward, and by vocal muscles within the cords that shorten the distance between thyroid and arytenoid cartilages. (For action of the laryngeal muscles in the production of sounds, *see* VOICE.)

Injury of the recurrent laryngeal nerves, or their more central connections, results in paralysis of all laryngeal muscles except the crico-thyroids.
